We experimented with the length of detector bit strings as suggested in Forrest et al. (1994), namely powers of 2 ranging from 32 to 256 for this value, which in our case is equal to  $n^2$ . Forrest et al. (1994) used a partial matching function that measures an amount of contiguous matches. Since our implemented initial detectors only use direct pixel comparisons, we could not take over their values directly. Instead for DPS we have performed some experiments with values between 0.5 and 1 for the threshold  $t$ . A too high threshold causes bad results because it means that every pixel in a group has to be equal to the other group, while a too low threshold causes that every picture is more likely to be highly similar to another. A threshold  $t$  of  $0.75n^2$  in combination with  $n = 4$  yields good results for DPS.

For ACDS the threshold was also manually tuned. In this case a too high threshold results into every picture being similar, while a too low threshold returns a similarity of at most 0. A threshold of 0.1 in combination with  $n = 16$  seemed to be nicely in the middle for ACDS.

The optimal value for the color range  $r$  was also determined by experimenting. Small values quickly start to give back topmost results which have 0% similarity. If  $r$  is set too high then everything is being returned as similar. A value of  $r = 30$  gives good results for most pictures. An exception is the city target image (see below) for which a value of  $t = 15$  gives better results.

### Parameters

After conducting many experiments we settled for  $n = 4$ ,  $t = 0.75 * n^2$ ,  $r = 30$  for DPS and  $n = 16$ ,  $t = 0.1$  for ACDS.

In the following, we will show results for three target images in different types of environments: city, scenery and an anemone in sea.

### City

The city target image is shown in Figure 7. It is characterised by a high diversity in the image.

Figure 7: City Target Image

Figure 8: Best Results for City Direct Pixel Similarity with  $n = 16$ ,  $t = 0.75 * n^2$ ,  $r = 15$ Figure 9: Best Results for City Direct Pixel Similarity with  $n = 16$ ,  $t = 0.75 * n^2$ ,  $r = 30$ 

Figure 8 and Figure 9 show the results for the DPS detector with  $r = 15$  and  $r = 30$ , respectively. These results clearly demonstrate the effects of the range value. If the range is set too high then different colors are considered similar. In the case of  $r = 30$  the first result can be explained by the characteristics of the target image. There is the blue sky and a dark part of the city. The pyramid photo shows exactly this pattern. If the range is set to a narrower value  $r = 15$ , better results are obtained.

The results of the ACDS detector for the city image are similar to those in Figure 9. This detector clearly has problems with the diversity in the city view.

### Scenery

A scenery target image considered is shown in Figure 10. It is characterised by a bright sky in the upper half and a darker soil in the lower half.

Figure 11 shows the resulting images for Direct Pixel Similarity. We can see that the most similar images that are returned resemble the characteristics of a bright sky in the upper half and a darker substance in the lower part, which corresponds with core characteristics of the target image.

Figure 12 shows the resulting images for Average Color Difference Similarity. Here the resemblance between pictures is still pretty high, but less distinct. For example in the output images number 8 and 3 a less clear distinction

Figure 10: Scenery Target Image

between the upper half and the lower half can be observed.

### Anemone

An Anemone target image in a sea environment is shown in Figure 13. It is characterised by shades of green over the whole image without a clear separation between the sky and the ground as in the scenery setting.

Figure 14 shows the resulting images for Direct Pixel Similarity. The top three results are exactly what we want to see. The rest of the images also contain similar shades

Figure 11: Best results for Scenery Direct Pixel Similarity with  $n = 4$ ,  $t = 0.75 * n^2$ ,  $r = 30$

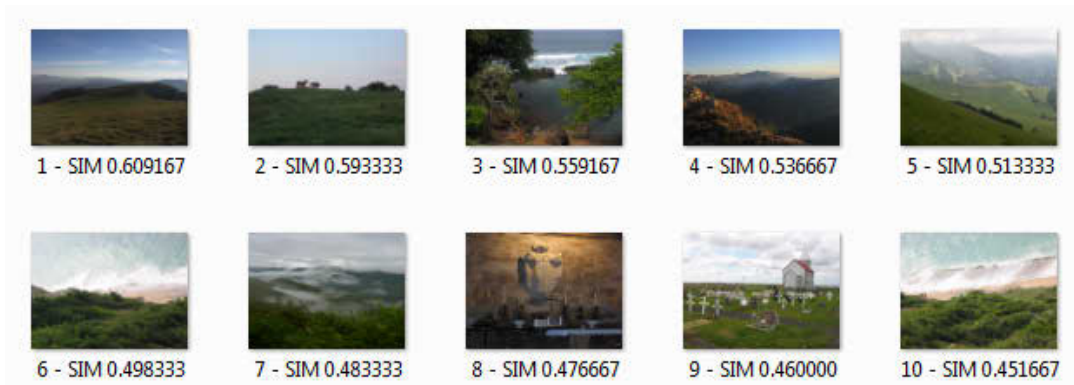

Figure 12: Best results for Scenery Average Color Difference Similarity with  $n = 16$ ,  $t = 0.1$

Figure 13: Anemone Target Image

of green as we would expect. However there are also less obvious hits such as 6, 8 and 10. This might be explained by the fact that the target picture has a lot of variation in pixel colors in each group.

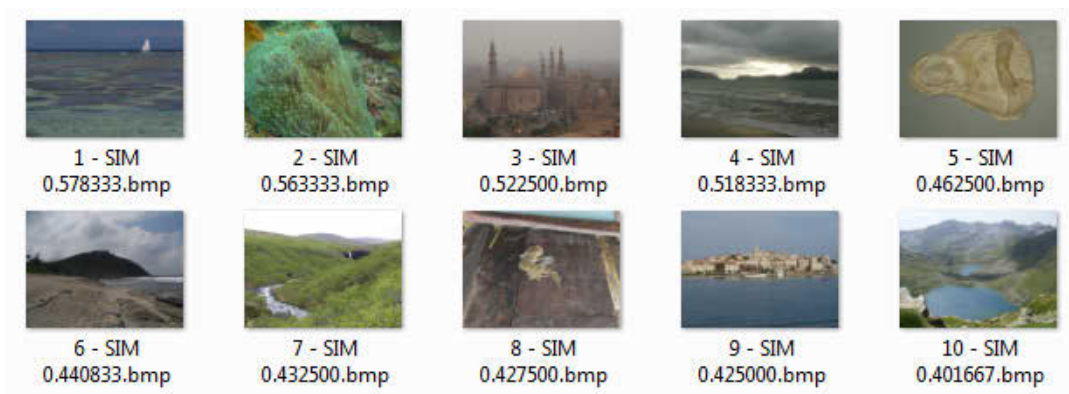

The Average Color Difference yields even worse results, see Figure 15, because it focusses on the average color in a group. This means that pictures which have many different

pixel colors within each group will have a higher probability of being similar to each other when they are averaged, which can yield strange results.

### Validation on labeled data

In order to assess the quality of the results automatically we consider a small dataset containing 60 images manually labeled according to three classes.

For each image, we remove it from the dataset and compute the average precision (see e.g. Müller et al. (2001)) over the entire ranking. Mean results over all images are reported in Table 1. In order to analyze the significance of these results, the average precision of each target image is compared to that of 1000 random rankings. Empirical p-values are then computed, as the fraction of times the average precision on random ranking was better than that on the ranking generated using NSA. The resulting p-values are 0.004 for ACDS and 0.001 for DPS. Results indicate that NSA is better than a (random) baseline method, that DPS and ACDS have similar variance, and that DPS performs better than ACDS.

Figure 14: Best results for Anemone Direct Pixel Similarity with  $n = 4, t = 0.75 * n^2, r = 30$ Figure 15: Best results for Anemone Average Color Difference Similarity with  $n = 16, t = 0.1$ 

| mean average precision<br>ACDS (std) | mean average precision<br>DPS (std) |
|--------------------------------------|-------------------------------------|
| 35.65% (3.39)                        | 41.82% (3.43)                       |

Table 1: Leave-one-out results on a manually labeled dataset with three classes. Mean average precision across the images; std denotes standard deviation.

## Discussion

This paper investigated the use of NSA for content-based image retrieval. We have introduced a simple method based on NSA and showed that it can achieve promising similarity search results on a collection of general-purpose images as assessed by human inspection.

In future work we plan to extend the proposed method by incorporating also detectors defined on dimensions such as texture and shape. This will allow to handle image collections of general-purpose images from various given categories. In this way, for each image, the sets of images from its category can be used as the ground truth in the evalu-

ation. Hence effectiveness measures such as average precision can be used to formally assess the performance of a method. This will allow us to perform a comparative assessment of the proposed method using state-of-the-art algorithms for this task.

The two detectors we have implemented are just two examples of what can be done to measure similarity. There are many more possibilities notably measures based on Earth Mover's Distance, which is a similarity measure between multidimensional distributions (Lv et al., 2004). Other similarity measures include contrast measurements, color matrices or even completely different approaches such as edge detection. If we can use these detectors together, possibly in parallel, the performance and resulting similarity might be improved even further.

Nevertheless the current results based on our simple method are already fairly similar to (manual) human eye selection, which is usually what a user of such a system would want. Our conclusion is therefore that Negative Selection Algorithms can indeed aid in creating a search system for image similarity search.

A number of aspects of this research remain to be investigated. For instance, adding non-determinism and random elements to detectors, thereby applying the algorithm more literally, could give more varied results, but also likely less precise. Detector coverage in such a non-deterministic scenario could then be improved by applying analytic methods (Ji and Dasgupta, 2005). Another possibility is increasing performance of this algorithm, either by better pre-processing of the data (see e.g. the methods described in the survey by Smeulders et al. (2000)), or by applying detectors in parallel.

## Abstract

Error detection and recovery are important issues in swarm robotics research, as they are a means by which fault tolerance can be achieved. Our previous work has looked at error detection for single failures in a swarm robotics scenario with the Receptor Density Algorithm. Three modes of failure to the wheels of individual robots was investigated and comparable performance to other statistical methods was achieved. In this paper, we investigate the potential of extending this approach to a robot swarm with multiple faulty robots. Two experiments have been conducted: a swarm of ten robots with 1 to 8 faulty robots, and a swarm of 10 to 20 robots with varying number of faulty robots. Results from the experiments showed that the proposed approach is able to detect errors in multiple faulty robots. The results also suggest the need to further investigate other aspects of the robot swarm that can potentially affect the performance of detection such as the communication range.

## Introduction

A robot swarm is robust to failure of individuals has always been a dominant view in swarm robotics research (e.g. (Bayindir and Şahin, 2007; Şahin et al., 2008)). It is expected that when an individual robot fails, the task left behind by the failed robot will be taken over by other robots in the swarm, and thus the swarm is robust. This view of a robust swarm has two underlying assumptions: the number of fault-free robots is significantly greater than the number of faulty robots, and that the failed robots do not interfere with other robots with respect to the operation of the swarm.

However, studies have demonstrated that the assumption that failed robots do not interfere does not hold for all modes of failure (Winfield and Nembrini, 2006). For a partly failed robot in which only some components are faulty whilst other components are still operational, the failed robot *can* and *will* interfere with the operation of the swarm. For example, in a swarm taxis scenario (swarm moving toward a beacon) investigated in Winfield and Nembrini (2006), a fault to the wheels while other components (e.g. wireless communication) are still operational causes physical anchoring of the robot swarm. Therefore, for such cases, there is a need to

handle these failures explicitly. One approach that is applicable for such cases is with explicit error detection and recovery. This approach consists of three stages: error detection, fault diagnosis, and recovery.

Error detection is a crucial first step as the activation of subsequent stages only occur when an error is detected. Previous studies on error detection in swarm robotics have looked at this problem for the case of a single faulty robot in the swarm. However, there is little work that directly addresses error detection when there are multiple (simultaneous) faulty robots in a swarm. In Christensen et al. (2009), the detection of faulty robots occur at the system-level for sensor faults that can be visibly detected by other robots. In Li and Parker (2009), fault detection is investigated for tightly-coupled multi-robot teams. In this paper, we investigate multiple faulty robots in the context of a foraging swarm robotic system in which the ability to forage for each robot can be affected by faults as well as the conditions in the operational environment.

Results from earlier work (Lau et al., 2011b,a) for a single faulty robot have demonstrated the potential of adaptive error detection with the collective self-detection (CoDe) scheme. In the CoDe scheme, a robot determines whether itself is faulty by cross-reference its behaviour with other robots within a logically defined neighbourhood. Each robot communicates (broadcast) its data to other robots in the same neighbourhood. The neighbourhood is defined by the communication range. If there are multiple failures in the same neighbourhood, the detection of faulty robots is harder and the CoDe scheme might work less effectively. This is because if there are more faulty robots in a neighbourhood, the CoDe scheme (which is analogous to a majority voting scheme) might (mis-)detect the fault-free robots as faulty, and vice versa. This is unwanted as the likelihood of multiple failures in a large swarm can be high (Carlson et al., 2004). Luckily, since the robots are mobile, the likelihood of a faulty robot in a neighbourhood of more faulty robots can be low. Besides, if the errors can be detected and recovered early, it can also reduce the likelihood of having multiple faulty robots in a neighbourhood.

The main contributions of this paper, therefore, are (1) an extended investigation on an immune-inspired CoDe scheme for multiple faulty robots in a swarm, (2) presentation on the calculation of the performance of detection for the case of multiple faulty robots, (3) an investigation on the correlation between the number of faulty robots and the required swarm size for effective error detection, and (4) the identification of the robot's communication range as a potential influencing factor on the performance of detection.

This paper is structured as follows. Section present the state-of-the-art on error detection in swarm robotics and the motivation of this paper. Section presents details on the set of experiments, and the experimental setup to investigate error detection for the case of multiple simultaneous faulty robots. Results from the experiments are presented in Section whilst Section concludes with the findings from the experiments in this paper.

## Background

There are many approaches for detecting errors in faulty robots. Generally, they can be grouped into model-driven and data-driven approaches. In model-driven approaches, analytical models of how a robot should behave are build and the actual behaviour is then compared to the predicted behaviour of the models. A problem with model-driven approaches is that the development of accurate models is often difficult, if not impossible, especially if the operational environment is not static or controlled (Christensen et al., 2007a). Due to the interactions between robots and the environment, as well as other natural factors, the state of the environment can change and this in turn can affect the behaviour of the robots.

Alternatively, a data-driven approach uses data produced during normal operation as the basis to infer the presence of a fault. This eliminates the need for precise analytical models of the robot's behaviour. In addition, it is possible to deploy the same robot swarm in many different environments. Therefore, data-driven approaches are generally more preferred.

Previous studies on data-driven error detection in swarm robotics have investigated scenarios of a single faulty robot in the swarm (e.g. (Canham et al., 2003; Christensen et al., 2007a,b; Lau et al., 2011b; Mokhtar et al., 2009)). However, having only one faulty robot in a robot swarm is a best-case scenario because the likelihood of multiple robots failing is high due to a variety of circumstances.

## From Single to Multiple Faulty Robots

The reason for the previous focus on a single faulty robot was that the proposed solution should scale to failure on multiple robots, as the detection is only based on data from one robot (e.g. (Canham et al., 2003; Christensen et al., 2007a; Mokhtar et al., 2009)). In other words, it is assumed that the changes in the behaviour of the robots are only

caused by faulty components. The environment in which the robot swarm operates has no impact on the behaviour of the robots. In this case, even with multiple faulty robots in the swarm, the detection of errors on each individual robot remained the same and unaffected by the number of faulty robots.

However, for many scenarios especially when the robot swarms are deployed in real-world environment, the operational environment does affect the behaviour of the robots. An example would be a robot foraging scenario in which the performance of foraging of each robot can not only be affected by the presence of faults but also by the amount of objects in the arena or the condition of the terrain. Therefore, instead of using data from a single robot, the CoDe scheme (Lau et al., 2011b,a) utilises data from a collective. The collective is defined over a logical neighbourhood based on the communication radius of an observer robot. In the CoDe scheme, the presence of a error is determined by cross-referencing a robot's behaviour with other robots within a neighbourhood. Results from the studies show that with the CoDe scheme, an adaptive error detection in the presence of time-varying environmental changes can be achieved.

As mentioned earlier, previous studies have only looked at error detection for a single faulty robot in the swarm. In practise, the probability of having multiple faulty robots in a swarm can be high. A survey on mobile robot failures in Carlson et al. (2004) found that the mean time between failures across all robot types surveyed is twenty four hours and the availability was fifty four percent. Indeed, the frequency of failure is very high.

To detect multiple faulty robots in a swarm is a challenging problem, in particular for scenarios in which the behaviour of the robots is affected by the operational environment as well as the presence of faults. First, detection approaches that operate on the basis of a single robot may not be applicable as changes in the environment that affect the behaviour may be detected as errors. This may lead to false positives. In Canham et al. (2003); Christensen et al. (2007a); Mokhtar et al. (2009), the robots are trained with a set of behaviour that is considered fault-free and thus the learning is static. During operation, changes in the environment that can affect the behaviour of the robots are not anticipated, and thus likely to cause the environmental changes to be detected as faults. Second, the assumption that there are more fault-free robots compared to faulty robots as employed in the CoDe scheme, might not be true for all scenarios. This is particularly in scenarios in which there are more faulty robots compared to fault-free robots in the neighbourhood. This leads to false negatives.

However, the fact that the robots are mobile minimises the frequency of such scenarios. The membership of robots in a logical neighbourhood is dynamic as the robots moves about in the arena. In addition, if errors can be detected early, the likelihood of having a neighbourhood with more

faulty robots can also be minimised. Therefore, this paper aims to investigate the following research questions

- Can the CoDe scheme be extended to multiple faulty robots?
- Is there any correlation between the swarm size and the number of faulty robots that can be detected with the CoDe scheme?

To investigate these research questions, the next two sections will provide details on the CoDe scheme, the evaluation metrics, and the set of experiments conducted.

## The Detection Framework

**The Detection Scheme** The detection of errors in faulty robots in this paper is based on the CoDe scheme proposed in Lau et al. (2011b,a). This scheme is analogous to a majority voting scheme (majority wins) which is the basis for social comparison when objective, non-social means are available (Festinger, 1954). However, the CoDe scheme is designed and implemented for self-detection of errors. Self-detection here means that instead of identifying whether other robots are faulty, it detects whether itself is faulty. This is inspired by the observed behaviour of self-isolation, to die alone, in ants. Instead of being actively located and isolated by healthy members, some species of ants infected by parasites tends to isolate themselves to die (Heinze and Walter, 2010). Taking this approach means that, at this stage, the detection can be more robust as it does not requires the identification of other robots in the swarm, as well as storing and keeping record of previous encounters with other robots. If the identification of faulty robots is required, it can be implemented on top of self-detection as proposed in Christensen et al. (2009). The pseudocode for the CoDe scheme is presented in Algorithm 1.

**The Classifier** The classifier used in this paper is the Receptor Density Algorithm (RDA) Owens et al. (2009) inspired by the T-cell receptor signalling mechanism in the immune system. By extraction of certain features of the generalised T-cell receptor, it was then mapped onto kernel density estimation. The RDA works as follow. The spectrum of input data is divided into  $s$  discretised location and a receptor  $\mathbf{x}_s$  is placed at each of these locations. The input data is the variable values from the robots used for the detection. A receptor has a length  $\ell = (\sqrt{2\pi})^{-1}$ , a position  $r_p \in [0, \ell]$ , and a negative feedback barrier  $\beta \in (0, \ell)$ . At each control cycle step  $t$ , each receptor takes input  $\mathbf{x}_i$  and performs a binary classification  $c_t \in \{0, 1\}$  to determine whether that location is considered anomalous. In general, the observation of one anomalous location is sufficiently representative to indicate the present of an anomaly at  $t$  (Owens et al., 2009).

The classification decision is determined by the dynamics of  $r_p$  and negative feedback  $r_n \in (0, \ell)$ . During training or

**end**

---

initialisation, after  $\mathbf{x}_i$  was presented, if the resulting  $r_p \geq \beta$  then a negative feedback  $r_n$  is generated which acts to reverse the progression of  $r_p$ . If  $r_p < \beta$ , no negative feedback will be generated,  $r_n = 0$ .

$$r_p(\mathbf{x}) = \sum_{i=1}^n \frac{1}{nh} K\left(\frac{\mathbf{x} - \mathbf{x}_i}{h}\right) \quad (1)$$

$$r_n(\mathbf{x}) = \begin{cases} r_p(\mathbf{x}) - \beta, & \text{if } r_p(\mathbf{x}) \geq \beta \\ 0, & \text{otherwise} \end{cases} \quad (2)$$

The receptor position and negative feedback decay over time. During testing, for a new data instance  $\mathbf{v}$  if  $r_p^t > \ell$ , then the receptor generates an anomaly classification  $c_t = 1$ .

$$r_p^t(\mathbf{x}) = b \times r_p^{t-1}(\mathbf{x}) + gb \times K\left(\frac{\mathbf{x} - \mathbf{v}}{h}\right) - a \times r_n^{t-1}(\mathbf{x}) \quad (3)$$

where  $b \in \mathbb{R}^+$  is receptor position's decay rate,  $gb \in \mathbb{R}^+$  is current input stimulation rate,  $a \in \mathbb{R}^+$  is negative feedback's decay rate.

$$c(\mathbf{v}) = \begin{cases} 1, & \text{if } r_p^t(\mathbf{x}) \geq \ell \\ 0, & \text{otherwise} \end{cases} \quad (4)$$

For the experiments in this paper, the  $K(\mathbf{x})$  in Eq. 1 and Eq. 3 is Gaussian kernel, the  $\beta = 0.01$ ,  $b = 0.02$ ,  $gb = 1.1$ , and  $a = 1.7$ .

## The Experiments

Two experiments are conducted: 1) an investigation of the potential of detecting errors in a swarm of multiple faulty robots with the CoDe scheme; 2) an investigation on the

correlation between the size of the swarm and the ability to detect errors.

**Fixed Swarm Size** This experiment investigates the robustness in detecting errors for multiple faulty robots with the CoDe scheme. The aim is to find out whether the approach that has been demonstrated to work well with a single faulty robot Lau et al. (2011b,a) can also be applied to the case of multiple faulty robots. More importantly, if the approach works with multiple failures then how will it degrade as the the number of failures increases.

In this experiment, faults are injected to robots in the system at 2500s (which is at control cycle 10). However, the fault models, number of faulty robots, and the duration for each fault are randomly generated. With a random number of faulty robots and fault durations, the number of faulty robots in a single simulation run can vary from one control cycle to another. For this reason, section describes how the performance is to be evaluated.

**Variable Swarm Size** This experiment investigates the possible correlation between the swarm size and the number of faulty robots that can be detected. This relates to the reliability of the error detection. The aim is to find a correlation  $n = ak + c$ , if exists, such that for  $k$  faulty robots there needs at least  $n$  robots in the swarm to ensure that the errors can be detected reliably with a true positive rate greater than or equals to  $x$ , a false positive rate of less than or equals to  $y$ , or both. For hardware redundancy, the number of redundant components generally suggested is  $2k + 1$  (Abd-El-Barr, 2006).

The configuration for the time of faults injection, number of faulty robots, duration for each fault in this experiment is the same as previous experiment. However, the swarm size is increased gradually starting from 10 robots. For every successive increment, an additional of two robot will be added.

## The Evaluation Metrics

The performance of detection is evaluated based on the performance is based on the true positive rate, false positive rate, and the (Latency), as in Lau et al. (2011a). Given:

- True Positive (TP) - an error is correctly classified;
- False Positive (FP) - a normal instance is incorrectly classified as an error;
- True Negative (TN) - a normal instance is correctly classified as normal; and
- False Negative (FN) - an error is incorrectly classified as a normal instance.

The True Positive Rate (TPR) is the proportion of the number of correctly classified errors over the total number of erroneous instances (Eq. 5).

$$TPR = \frac{TP}{TP + FN} \quad (5)$$

Similarly, the False Positive Rate (FPR) is the proportion of the number of incorrectly classified errors over the total number of normal instances (Eq. 6).

$$FPR = \frac{FP}{FP + TN} \quad (6)$$

The (Latency) metric evaluates how long the time has elapsed before an error is positively identified (Eq. 7). Given that  $t_{pd}$  is the fault detection time, and  $t_{ft}$  is the fault injection time, then

$$Latency = t_{pd} - t_{ft} \quad (7)$$

We present how TPR and FPR can be calculated for multiple faulty robots with reference to Figure 1. In the figure, there are ten robots in the system, labelled R1 to R10. In Figure 1(a), seven robots are faulty from time  $t=10$  onwards. However, the durations of faults between the robots are different as indicated by the black-coloured bar. For example, the fault in R1 lasts for 4 control cycles, from  $t=10$  to  $t=14$ . Since the durations faults are different, the number of faulty robots at each control cycle also differs. From  $t=10$  to  $t=11$ , there are seven faulty robots whereas from  $t=14$  to  $t=15$  there is only one faulty robot. By analysing the simulation data in this way, the TPR and FPR for each number of faulty robots can be calculated. For the scenario in Figure 1(a), there are instances for seven, six, five, three, and one faulty robot(s).

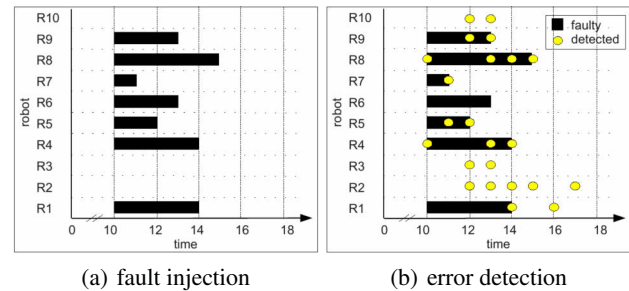

Figure 1: An illustration to show the calculation of TPR and FPR given information regarding the fault injection time, duration of fault, and detected errors.

In Figure 1(b), the circles represent the instances of error being detected. It can be seen that there are many instances of false positive (detection of error even when no fault was injected), e.g. with robots R2, R3, and R10. To calculate the TPR and the FPR, starts at  $t=11$ . At  $t=11$ , there are seven faulty robots. Therefore, the TPR for the case of seven faulty robots is  $2/7$ . Similarly, the FPR is  $0/3$ . At  $t=12$ , the TPR for six faulty robots is  $2/6$  whilst the FPR is  $3/4$ , and so on.

## Experimental Setup

The experiments in this paper were carried out in simulation. The context of the work is a robot swarm in a foraging scenario. The source code for the foraging swarm robotic system, data, and scripts used to produce results for this paper are available at <http://sites.google.com/site/huikenglau/shared>.

### Simulation Settings

The software used to implement the foraging robot swarm is the Stage plug-in (Gerkey et al., 2003). The robot swarm is placed in an arena to continuously locate, transport, and deposit objects until the end of simulation. At any time, a random number of robots can fail.

**Arena** The arena is an octagonal-shaped area of  $12\text{m} \times 12\text{m}$  with a circular base of  $3\text{m}$  in diameter in the centre. Objects are placed at random<sup>1</sup> locations but outside of the base at a default object-replenishing-rate (OPR) of 0.10. This means that the probability of adding an object at every second is 0.10.

**Robot** The physical robot from which the simulation model was based is the Linuxbot from Bristol Robotics Laboratory<sup>2</sup>. Each robot is equipped with an array of sensors and components needed for foraging. The default moving speed of the robots is  $0.15 \text{ m.s}^{-1}$  with a communication range of  $2\text{m}$ .

**Fault** Each robot in the swarm is subject to a particular fault in the wheels whilst other components are still functioning, as examined in Winfield and Nembrini (2006). Three models of faulty wheels were simulated: complete  $P_{CP}$ , partial  $P_{PT}$ , and gradual  $P_{GR}$ . The  $P_{CP}$  causes the wheels of a robot to stop responding completely and thus the robot is unable to proceed with foraging. With  $P_{PT}$ , the robot moves with a reduced speed and thus resulting in less objects being collected when compared to a fault-free condition. With  $P_{GR}$ , the robot moves with a gradually reducing speed until eventually it comes to a complete stop. In simulation,  $P_{CP}$  is simulated by setting the left wheel to left turn by  $10^\circ$  causing the robot to move in circle. For  $P_{PT}$ , the robots move with a reduced speed of  $0.45 \times 10^{-1} \text{ ms}^{-1}$  whilst for the  $P_{GR}$  the speed of the robot is reduced by  $0.10 \times 10^{-3} \text{ ms}^{-2}$ . The mode of the fault is transient; the fault lasts for a random period of time and then the robot recovers and continue with normal operation.

**Environment** Two different scenarios in which the robot swarm operates: constant OPR (CST), varying OPR ( $V_{OPR}$ ). In a CST scenario, the OPR is fixed at 0.10. On the other

hand, in a  $V_{OPR}$  scenario, the OPR alternates between 0.10 to 0.01 at different intervals.

**A Simulation Run** A simulation starts with 100 initial objects placed randomly in the arena. A maximum number of objects in the arena at any one time is capped at 400 units to avoid overcrowding. Each object is a small red coloured square box which can be sensed by the camera on each robot and picked up by the grippers on the robot. Robots depart from the base and the heading for each robot  $R_i$  is based on the formula  $R_i = \frac{i \times 2\pi}{n}$ ,  $n$  is the number of robots in the swarm. The robots will continuously carry out foraging until the end of the simulation. In this paper, each simulation lasts for 10,000s. Periodically (i.e. every control cycle, 250s), data on the number of objects collected `obj`, energy used `eng`, and distance travelled `dist` for each robot are extracted and output as csv files. For each variable, an instance of the CoDe scheme is executed separately and an error is considered detected if it is reported in at least one of the variables. The  $h$  in Eq. 1 for `obj` = 1.0, `eng` = 12.0, and `dist` = 2.5

## Experimental Results

### Fixed Swarm Size

Figure 2 is the result for the TPR and FPR in detecting errors for different number of faulty robots in a CST scenario. Each point in the graphs represent the TPR or FPR calculated over 100 repeated runs. Note that since the number of faulty robots and the duration of each fault are random, the number of instances for each group of faulty robots also differs. For example, out of the 100 runs, there are 1208 instances of eight faulty robots, 777 instances for seven faulty robots, 948 instances of six faulty robots and so on.

Figure 2: The TPR and the FPR for detecting multiple faulty robots in a CST scenario with the CoDe scheme.

In Figure 2, the results show that as the number of faulty

<sup>1</sup>The random number generator used is from GSL-GNU Scientific Library.

<sup>2</sup><http://www.ias.uwe.ac.uk/Robots/linuxbot.htm>

robots increases, the performance of detection decreases. Note that in this experiment, no recovery is included. Therefore, a TPR of 1.00 with one faulty robot means that the errors in that faulty robot can always be detected. Similarly, a TPR of 0.55 with eight faulty robots means that there is 55% chance that the errors in all eight faulty robots will be detected. This is possible because there are still two fault-free robots for the faulty robots to cross-referencing their data. In addition, because of the dynamic neighbourhood of the robots from one control cycle to another, a faulty robot might also be cross-referencing its data against others from the previous control cycle (refer line 5 in Algorithm 1).

The results show that with every increase of one faulty robot, the TPR decreases at an approximately constant rate of 0.10. This means the probability of detecting errors in all faulty robots decreases as the number of fault-free robots decreases. This is expected because the likelihood of more than one faulty robot in the logical neighbourhood is increased, and thus resulting in more false negatives. Similarly, the increase of the number of faulty robots also increases the FPR. The increase in the FPR is also approximately 0.10 for each addition of one faulty robot. Due to the same reason for the TPR, each addition of faulty robot increases the likelihood of fault-free robots to classify itself as faulty (false positives).

The result for the Latency in detecting the errors is shown in Figure 3. From the 100 runs, the median Latency is 1 control cycle. This means that the errors are detected in the next control cycle after faults were injected. This is a positive result because if recovery measures were implemented, the number of multiple simultaneous faulty robots can be reduced.

Figure 3: The Latency in detecting the models of fault of the wheels in a CST and a  $V_{OPR}$  scenario. The '+' points on the boxplots are the outliers.

The graphs in Figure 4 compares the performance between a CST and a  $V_{OPR}$  scenario. Overall, there is no significant difference between the performance in the TPR and the FPR. The drop in the TPR and the increase in the FPR as the number of fault robots increases are similar to the results for a CST scenario. In fact, some of the results for the  $V_{OPR}$  scenario are better than the CST scenario. This

is because even with a fixed OPR, the presence of multiple faulty robots can significantly affect the ability to positively identify errors. Nevertheless, this result shows that CoDe scheme works well in a non-dynamic as well as a dynamic environment even with multiple faulty robots in the swarm. This is encouraging as it further supports that the CoDe scheme can be adaptive to dynamic environments.

Figure 4: The TPR and FPR in detecting errors for a robot swarm with multiple faulty robots in a CST and a  $V_{OPR}$  scenario.

### Variable Swarm Size

Figure 5 show the TPR and FPR for multiple faulty robots with different swarm sizes. A general observation is that as the swarm size increases, the performance of detection also improves. For example, on the x-axis with two faulty robots in Figure 5(a), as the swarm size is increased from 10 robots to 18 robots, the TPR also increases (from about 0.85 to slightly above 0.90). Similarly in Figure 5(b) with two faulty robots, as the swarm size increases from 10 to 18 robots the FPR decreases from about 0.20 to less than 0.10.

However, note that the increase in the TPR does not occur in all cases. In some cases, rather counter-intuitive. For example with eight faulty robots in Figure 5(a), the TPR decreases from slightly below 0.60 to only above 0.50 when the swarm size increases. This observation is interesting and worth further investigation. One particular factor comes to mind is the communication range of each robot. This parameter influences the size of the logical neighbourhood. Here, it is set to 2m radius. From the results, it appears that an increase in the swarm size does not guarantee an increase in the neighbourhood size (i.e. the number of robots in the neighbourhood) at each control cycle. Therefore, this aspect will be investigated in the near future.

From this result of varying swarm size, the required swarm size for different number of faulty robots can be calculated. For example, in order to not falsely detect errors at 80% of the time in a swarm with four or less faulty robots (i.e.  $FPR = 0.80$ ) the swarm needs to have at least 12 robots. Similarly, with six or less faulty robots, a swarm of at least 16 robots is needed. From this trend, it seems that a swarm of  $n = k + 10$  is required to achieve a FPR less than 0.20 with  $k$  faulty robots.

(a) TPR

(b) FPR

Figure 5: The TPR and FPR in detecting errors for different swarm sizes.

Based on the same analysis, to be able to detect four faulty robots or less at 80% of the time (i.e.  $TPR = 0.80$ ), the swarm needs to have more than 20 robots. Unlike the TPR, based on current results, it is impossible and unrealistic to extrapolate the required swarm size with more than four faulty robots.

A general observation is that the swarm size required is greater than  $2k + 1$ . This is comparable to the generally used hardware redundancy Abd-El-Barr (2006). The reason is that in swarm robotics the robots are mobile and there is no guarantee that for  $k$  faulty robots, there will be at least  $2k + 1$  fault-free robots in the same logical neighbourhood. This observation hints that there are other factors involved and one particular parameter that came to mind is the communication range of the robots. For confirmation, this parameter will be investigated in the near future.

### Comparison with Q-test

The performance of error detection with multiple faulty robots using the CoDe scheme with the RDA is compared

with the Q-test (Gibbons, 1994) (Table 1, Table 2). Dixon's Q test (Gibbons, 1994), or simply the Q-test, is a non-parametric technique that can be used for error detection. It has been applied for error detection in the case of a single faulty robot in Lau et al. (2011a) and shown to produced the best results when compared to other statistical classifiers such as T-test, Quartile-based, and Extreme Studentised Deviate.

In Table 1, the RDA has consistently achieved a higher TPR when compared to the Q-test from all swarm sizes (from 10 to 20). However, a similar result is not obtained for the FPR (Table 2). When the number of faulty robots increases the FPR for the RDA increases. From the perspective of the CoDe scheme (i.e. majority voting), this is expected, in particular when the number of fault-free robots is significantly less than the number of faulty robots. Having said that, a more detailed investigation will be conducted in the near future.

Table 1: The difference of the TPR of the RDA and the Q-test (i.e. RDA-Q-test) in detecting errors with multiple faulty robots. Note that for the TPR, a positive value means a better result.

| No. Faulty robots | 10   | 12   | 14   | 16   | 18   | 20   |
|-------------------|------|------|------|------|------|------|

| 18                |      |      |      |      |      | 0.09 |

### Conclusion

We have presented our initial investigation on error detection for multiple faulty robots in the swarm. Specifically, we looked at scenarios in which the behaviour of the robots can be affected by both faulty components and changes in the environment. In addition, the way to calculate the performance metrics, namely the true positive rate, false positive rate, and latency for the case of multiple faulty robots are also presented. Revisiting the research questions, results from the first experiment give evidence that the CoDe scheme, which work for a single faulty robot, performs well for multiple faulty robots. In the second experiment, the general results show that as the swarm size is increased, the performance in detecting errors with multiple faulty robots also increases. In particular, the size of the swarm needs to be greater than

Table 2: The difference of the FPR of the RDA and the Q-test (e.e RDA-Q-test) in detecting errors with multiple faulty robots. Note that for the FPR, a negative value means a better result.

| No. Faulty Robots | 10    | 12    | 14    | 16    | 18    | 20    |

## The use of Agent-based Simulation to Discover Extreme Cases in Immune-Interactions with Early-Stage Cancer Scenarios

Early-stage cancer and its interactions with the immune system are still not fully understood. In order to better understand these processes, researchers employ different methods. Simulation and in particular, agent-based simulation (ABS) have been found useful tools for understanding it (Look et al., 1981; Castiglione et al., 1999, 2001; Bonabeau, 2002; Figueredo and Aickelin, 2011; Figueredo et al., 2013a,b).

In a previous study (Figueredo et al., 2013b) we have built an ABS model to study the interplay of immune cells and early-stage cancer. The model considers interactions between tumour cells and immune effector cells, as well as the immune-stimulatory and suppressive cytokines IL-2 and TGF- $\beta$ . IL-2 molecules mediate the immune response towards tumour cells. They interfere on the proliferation of effector cells according to the number of tumour cells in the system. Conversely, TGF- $\beta$  stimulates tumour growth and suppresses the immune responses by inhibiting the activation of effector cells and reducing tumour-antigen expression.

In order to validate our model, we used a well-established mathematical model found in the literature (Arciero et al., 2004). While at average both models do not show a statistical significant difference, some additional trends in the results of the ABS model are observed. As ABS is a stochastic simulation method, it was run for multiple times. Instead of having one solution, as it is the case for a deterministic mathematical model, ABS produces a variety of outcomes. These solutions are usually very similar. In our cases study, however, we could observe some instances which could not have been observed by using analytical methods (see Figure 1).

The use of ABS modelling has therefore led to the discovery of additional “rare” patterns, which we would have not been able to derive by using analytical methods. These “extreme cases” indicate that there might be circumstances where the tumour cells are completely eliminated by the immune system, without the need of any cancer therapies. We strongly believe that the observed emergent behaviour produced by stochastic simulation can make a useful con-

tribution to assisting immunological research. With the additional information supplied from the ABS, immunologists can test new hypotheses and further investigate whether these extreme cases actually occur in reality and why.

Currently, we are working on a methodology for defining experimental conditions that would allow us to observe similar emergent behaviour in other simulation experiments related to early-stage cancer research. One important aspect here is to investigate the statistical conditions under which emergent behaviour starts to appear. The questions we are looking at are:

1. How many replications of our stochastic simulation do we have to run before we can expect to see rare behaviours?
2. Is there any regularity in the growth of these rare emerging patterns?
3. What are the factors that need to be considered when predicting the occurrences of emerging patterns (e.g. level of dynamics in the model)?

The patterns obtained in our previous work were a result of 50 independent runs of the ABS model (Figueredo et al., 2013b). In order to further advance our knowledge regarding these patterns we are currently running experiments with 10,000 independent runs in order to verify whether there is any regularity in pattern growth. We also intend to validate our results with immunologists. It is hoped that the development of a methodology to further investigate extreme cases could assist in defining suitable vaccination strategies and the appropriateness of cancer treatments by the prediction of the possible outcome scenarios and how frequently they take place.

### Acknowledgements

This work was supported by the Advanced Data Analysis Centre (ADAC) at the University of Nottingham. The research leading to these results has also received funding from Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq) and FAPERJ (grant E-26/102.025/2009).

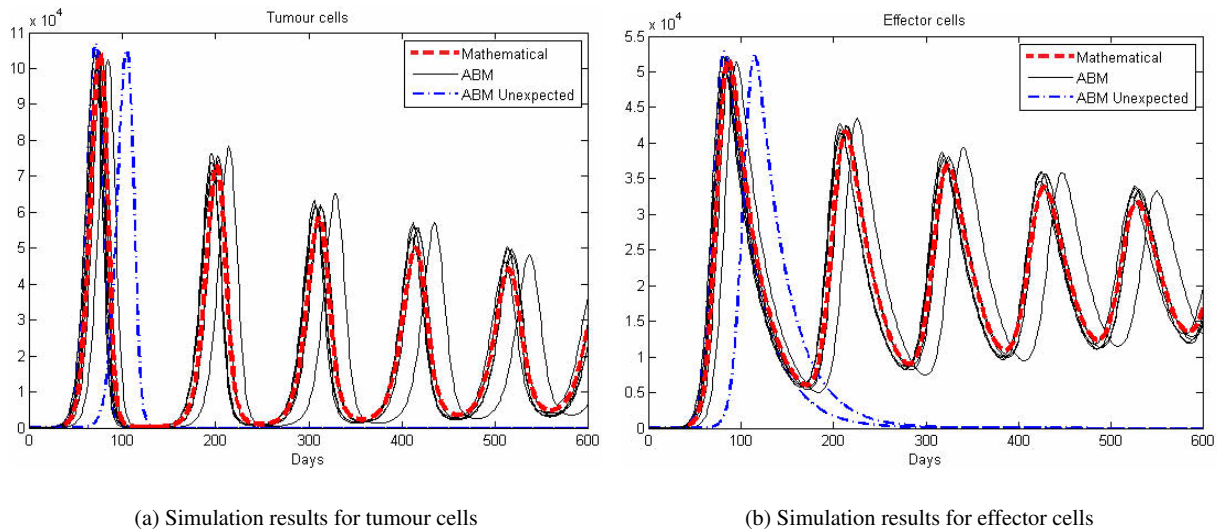

Figure 1: Simulation results: the dashed line (red) shows the mathematical output; the lines in black show exemplar ABS results for 6 runs. As it can be seen, there are some results very close to the mathematical formulation and others presenting more variability due to the ABS stochastic behaviour. These variations, however, follow the same pathway as the analytical solution. The dashed-dotted line (blue) shows the rare cases determined by the ABS simulations.

## Abstract

Motivated by the natural immune system's ability to defend the body by generating and maintaining a repertoire of antibodies that collectively cover the potential pathogen space, we describe an artificial system that discovers and maintains a repertoire of *heuristics* that collectively provide methods for solving *problems* within a problem space. Using bin-packing as an example domain, the system continuously generates novel heuristics represented using a tree-structure. A novel affinity measure provides stimulation between heuristics that cooperate by solving problems in different parts of the space. Using a test suite comprising of 1370 problem instances, we show that the system self-organises to a minimal repertoire of heuristics that provide equivalent performance on the test set to state-of-the-art methods in hyper-heuristics. Moreover, the system is shown to be highly responsive and adaptive: it rapidly incorporates new heuristics both when entirely new sets of problem instances are introduced or when the problems presented change gradually over time.

## Introduction

Heuristic search methods have been shown to be successful in solving a wide-range of real-world problems. Typically for a given application domain, a range of heuristics for solving problems will exist; these might range in nature from simple rules encapsulating expert knowledge to complex search algorithms that need to be tuned by experts to work. Commonly, different heuristics will work well on problems in different parts of the *problem space*. By collecting together a set of heuristics, it is hoped that collectively, the weaknesses of individual heuristics can be compensated for by other heuristics in the set (Burke et al., 2003). The goal of the *hyper-heuristics* field is to find automated methods that can both generate appropriate sets of heuristics and provide a means of selecting between heuristics in the set, given either a new problem instance or even a partially solved problem instance.

While such approaches have proved successful in many application areas, most hyper-heuristic approaches fail to *continuously* learn from experience. On the one hand, the failure to exploit previous knowledge leads to inefficient hyper-heuristics; on the other, if the characteristics of instances of problems in the domain change over time, a

hyper-heuristic may need to be completely re-tuned or in the worst case redesigned periodically. An 'ideal' hyper-heuristic would be able to exploit previous knowledge through access to some kind of memory, rapidly adapt existing knowledge to new circumstances, and additionally, generate new knowledge when previous knowledge is not applicable.

We observe that the immune system fulfils very similar properties in its role as a host maintenance and defence system. The immune system maintains a repertoire of antibodies that has been shown theoretically to cover the space of potential pathogens. Clonal selection mechanisms provide a means of rapidly adapting existing antibodies to new variants of previous pathogens; meta-dynamic processes are able to generate novel antibodies; a memory mechanism enables the immune system to respond rapidly when faced with pathogens it has previously been exposed to.

Using this analogy, we present a system that is shown experimentally to outperform single human-designed heuristics by a significant margin and furthermore, is shown to be more adaptable and responsive than a recent state-of-the-art hyper-heuristic approach when faced with a continually changing problem landscape, thereby addressing the needs of real-world practitioners more fully. The novel system described has the following features:

- it generates novel heuristics from a library of component parts
- it utilises meta-dynamic processes to both add and remove heuristics from the system resulting in a self-organising network of heuristics
- it sustains a network of interacting heuristics of minimal size that collectively solve problems from the whole of the problem space
- it encapsulates memory in the sustained network enabling rapid adaptation to new problems

## Background

We briefly cover some background in relation to the tested application domain of bin-packing and outline the immunol-

ogy that inspired this approach before describing the system in detail.

## Immunology

Artificial Immune Systems (AIS) algorithms have been applied in many domains, including solving combinatorial optimisation (CO) problems (Kromer et al., 2012). Unlike other biologically inspired paradigms there is no de-facto model used by AIS practitioners. Of the models used the one most frequently applied to CO problems is *clonal selection theory* (Burnet, 1959), however, many other paradigms exist: we exploit the *idiotypic network* (Jerne, 1974) model in this work, in part due to its plasticity and its ability to describe the memory mechanism exhibited by the immune system.

Idiotypic network inspired models have been developed to address machine learning problems such as clustering (Neal, 2003), however the most relevant line of work in relation the model proposed in this article is in the robotics domain. An idiotypic network model to perform behaviour arbitration in mobile robots was one of the first applications in AIS (Watanabe et al., 1998) and spawned subsequent related work. In these early approaches, antibodies in the network represented behaviours (actions); antibodies were stimulated by environmental conditions and further suppressed or stimulated by interactions with other antibodies in a modified version of Farmer's original equation (Farmer et al., 1986). The immune repertoire consisted of a set of antibodies which collectively covered a space of appropriate actions required to achieve the robot goals in the space defined by environment. In this early work, antibodies were pre-defined; research focused on evolving connections and matching strengths between antibodies. In more recent work, Whitbrook *et al* have extended earlier work by using an evolutionary algorithm in separate learning phase to produce antibodies which are used to seed the network. The benefits of seeding the network with a diverse and novel set of antibodies are described in Whitbrook et al. (2010).

In this paper, we adopt a similar approach to Whitbrook *et al* in recognising the need to develop a diverse set of antibodies for potential inclusion in the network. In contrast to previous work however, our mechanism is not just used to seed the network in an initial phase but continuously generates a stream of potential antibodies which are either incorporated into the network or rejected according to a meta-dynamic process. This results in a learning scheme in which the network is able to continuously adapt over time.

## HyperHeuristics

Originally described as “*heuristics to select heuristics*” (Burke et al., 2003) the field of hyper-heuristics has evolved to also encompass “*heuristics to generate heuristics*” (Burke et al., 2010); both methods have the common goal of searching a landscape defined by the heuristics in order to find a procedure for solving a problem, rather than

searching directly over the solution space defined by the problem itself. Hyper-heuristic methods have been widely applied to bin-packing problems. We discuss the most relevant research briefly below.

**Heuristic generation** Genetic Programming (GP) is typically used a method of generating new heuristics. In Burke et al. (2006, 2012) GP was used to automate the design of heuristics for the bin-packing problem in multiple dimensions. Using a small set of benchmarks, they found the generated heuristics to be competitive with human-designed heuristics. In Sim and Hart (2013), the authors introduced Single Node Genetic Programming as a method to evolve new heuristics for bin-packing. SNGP, introduced in Jackson (2012), differs from the conventional GP model introduced by Koza (1992) in a number of key respects. A single tree structure is used to represent a population of possible trees by allowing any node to be the start node. Only mutation is used to change connections with the tree, alleviating the undesirable affect of *bloat* found in conventional GP and enabling different network structures to emerge in addition to classical tree structures.

**Heuristic selection** Most hyper-heuristics use a *fixed* set of low-level heuristics (whether generated or hand-built) and define or learn a model to select an appropriate heuristic based on the current state of the problem or a description of the problem characteristics. In contrast, Sim and Hart (2013) introduce an island model based on the concept of *Cooperative Coevolution* (Potter and De Jong, 2000) in which a set of islands each contribute a heuristic to a collaborating set that collectively are able to solve a problem. Crucially, the number of islands is not prefixed but is adaptable. In Sim and Hart (2013), an island contains a population described using SNGP; each island contributes its best heuristic to the collaboration set. Based on a set of 685 test instances, the authors showed that the model was able to solve more instances and reduce the number of extra bins required than an equivalent sized set of man-made heuristics from the literature.

In the current work, a simplified version of SNGP is used to generate novel heuristics and the island model described above is replaced by an AIS algorithm which is shown to be able to find, maintain and adapt a collaborating set of heuristics that equals or outperforms other previous approaches.

## 1D BPP and Benchmarks

The objective of the one dimensional bin packing problem (BPP) is to find a packing which minimises the number of containers,  $b$ , of fixed capacity  $c$  required to accommodate a set of  $n$  items with weights  $\omega_j : j \in \{1 \dots n\}$  falling in the range  $1 \leq \omega_j \leq c, \omega_j \in \mathbb{Z}$  whilst enforcing the constraint that the sum of weights in any bin does not exceed the bin capacity  $c$ . The lower and upper bounds on  $b$ , ( $b_l$  and

$b_u$ ) respectively, are given by equation 1. Any heuristic that does not return empty bins will produce, for a given problem instance,  $p$ , a solution using  $b_p$  bins where  $b_l \leq b_p \leq b_u$ .

$$b_l = \left\lceil \sum_{j=1}^n \omega_j \div c \right\rceil, \quad b_u = n \quad (1)$$

Table 1 shows the parameters from which the benchmark problem instances used in this study were generated. Data sets *ds1*, *ds2* & *ds3*, introduced by Scholl et al. (1997) all have optimal solutions that vary from the lower bound given by Equation 1. However all are known and have been solved since their introduction (Schwerin and Wäscher, 1997). All of the instances from *FalU* and *FalT*, introduced by Falkenauer (1996), have optimal solutions at the lower bound except for one (Gent, 1998).

Six deterministic heuristics commonly cited in the literature are used for comparison — FFD, DJD, DJT, ADJD, BFD and SS. Descriptions of each of these heuristics can be found in Sim and Hart (2013). Note that in the implementation used here, each deterministic heuristic is presented with each problem instance's items pre-sorted in descending order of size.

## Implementation

The system comprises of three main parts: a database of problem instances, a heuristic generator and the AIS as illustrated by Figure 1.

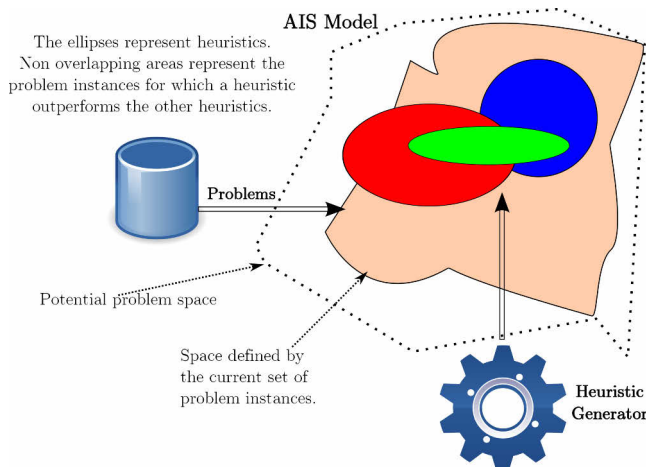

Figure 1: System Model

The system is designed to run continuously; problem instances can be added or removed from the system at any point. A heuristic generator akin to *gene libraries* in the natural immune system provides a continual source of potential heuristics. The AIS itself consists of a set of heuristics (akin to *antibodies in the natural immune system* that interact with each other based on an *affinity metric*. The overall goal of

the system is to develop a repertoire of heuristics that can solve the set of problem instances to which they are currently exposed and that can adapt its structure and constituent parts as the problem instances change in nature. The component parts are described in detail below.

## Heuristic Generator

Heuristics are represented using a tree structure and are generated using only the *initialisation* process used in SNGP (Jackson, 2012) resulting in structures as shown in the example given in Figure 2 — this tree shows one of the deterministic heuristics from the literature DJD encoded in a tree format. A fixed set of terminal and function nodes are available to the generator and are defined in Table 2 which combines nodes according to the process outlined in Algorithm 1. Further details outlining the justification for the choice of nodes and further details on the SNGP process can be found in Sim and Hart (2013). One heuristic is generated per iteration of the AIS algorithm.

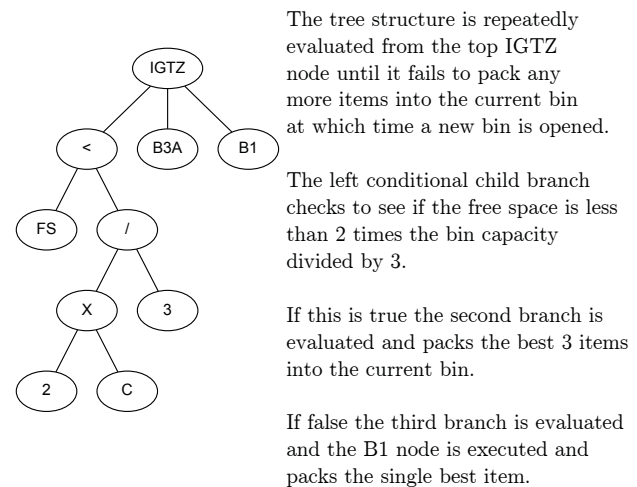

Figure 2: DJD Heuristic Expressed as a Tree

## Algorithm 1 Heuristic Generation

- 1: Each of the terminal nodes  $T \in \{t_1, \dots, t_r\}$  are added exactly once. The terminal nodes are given an integer identification number ranging from  $1 \dots r$ .
- 2: A number,  $n$ , of function nodes are selected at random from the set of all function nodes  $F \in \{f_1, \dots, f_s\}$  and given an identification number ranging from  $r + 1, \dots$  to  $r + n$ . This allows for the possibility of duplicate function nodes within the population or for SNGP structures with function nodes omitted.
- 3: The function nodes have all their child nodes assigned at random from nodes with a lower id thus preventing any infinite looping.
- 4: A single node is chosen at random to be the root node.

Table 1: Data sets *ds1*, *ds3* and *FalU* were created by generating  $n$  items with weights randomly sampled from a uniform distribution between the bounds given by  $\omega$ . Those in *FalT* were generated in a way similar to Falkenauer (1996) so that the optimal solution has exactly 3 items in each bin with no free space. Scholl's *ds2* was created by randomly generating weights from a uniform distribution in the range given by  $\varpi \pm \delta$ . The final column gives the number of instances generated for each parameter combination.

| Data Set    | capacity ( $c$ ) | $n$              | $\omega$                  | #Problems            |
|-------------|------------------|------------------|---------------------------|----------------------|
| <i>ds1</i>  | 100,120,150      | 50,100,200,500   | [1,100],[20,100],[30,100] | $36 \times 20 = 720$ |
| <i>ds3</i>  | 100000           | 200              | [20000,30000]             | 10                   |
| <i>FalU</i> | 150              | 120,250,500,1000 | [20,100]                  | $4 \times 20 = 80$   |
| <i>FalT</i> | 1                | 60,120,249,501   | [0.25,0.5]                | $4 \times 20 = 80$   |

| Data Set   | $c$  | $n$            | $\varpi$ (avg weight)                                | $\delta$ (%) | # Problems           |
|------------|------|----------------|------------------------------------------------------|--------------|----------------------|
| <i>ds2</i> | 1000 | 50,100,200,500 | $\frac{c}{3}, \frac{c}{5}, \frac{c}{7}, \frac{c}{9}$ | 20,50,90     | $48 \times 10 = 480$ |

Table 2: Nodes Used

#### Function Nodes

|      |                                                                                                                                                                                            |
|------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| /    | Protected divide returns -1 if denominator is 0 otherwise the result of dividing the first operand by the second                                                                           |
| >    | Returns 1 if the first operand is greater than the second or -1 otherwise                                                                                                                  |
| IGTZ | Evaluates the first operand. If it evaluates as greater than zero the result of evaluating the second operand is returned otherwise the result of evaluating the third operand is returned |
| <    | Returns 1 if the first operand is less than the second or -1 otherwise                                                                                                                     |
| X    | Returns the product of two operands                                                                                                                                                        |

#### Terminal Nodes

|     |                                                                                                                                                             |
|-----|-------------------------------------------------------------------------------------------------------------------------------------------------------------|
| B1  | Packs the single largest item into the current bin returning 1 if successful or -1 otherwise                                                                |
| B2  | Packs the largest combination of exactly 2 items into the current bin returning 1 if successful or -1 otherwise                                             |
| B2A | Packs the largest combination of up to 2 items into the current bin giving preference to sets of lower cardinality. Returns 1 if successful or -1 otherwise |
| B3A | As for B2A but considers sets of up to 3 items                                                                                                              |
| B5A | As for B2A but considers sets of up to 5 items                                                                                                              |
| C   | Returns the bin capacity                                                                                                                                    |
| FS  | Returns the free space in the current bin                                                                                                                   |
| INT | returns a random integer value $\in (-1, \dots, +5)$                                                                                                        |
| W1  | Packs the smallest item into the current bin returning 1 if successful else -1                                                                              |

## AIS

The AIS component is responsible for constructing a network of interacting heuristics and for governing the dynamic

processes that enable heuristics to be incorporated or rejected from the current network. These two aspects are now described.

**Affinity** A key aspect of this is the *affinity metric* that defines the manner and the extent to which heuristics can interact. In the natural immune system, affinity is defined by physical and chemical interactions between molecules of different shape, with molecules with *complementary* structures showing highest affinity (the well known lock-and-key analogy). We re-interpret the notion of complementarity in the heuristic space as follows:

**Definition** Heuristic  $H_A$  is complementary to Heuristic  $H_B$  if Heuristic  $H_A$  uses fewer bins than Heuristic  $H_B$  on at least one problem instance

The *affinity* of Heuristic  $H_A$  for Heuristic  $H_B$  is equal to the number of extra bins  $\Delta b_{abp}$  used by Heuristic  $H_B$  summed across the set of  $l$  problem instances available to the system, and is defined in equation 2. Note that affinity between two heuristics is asymmetrical.

$$\alpha_{ab} = \sum_{p=1}^l \Delta b_{abp} \begin{cases} \Delta b_{a_p b_p} = b_{b_p} - b_{a_p} & : \text{if } b_{a_p} < b_{b_p} \\ \Delta b_{a_p b_p} = 0 & : \text{otherwise} \end{cases} \quad (2)$$

The total *stimulation* experienced by a heuristic is the sum of the affinities with all other heuristics in the network and is given by Equation 3 where there are  $m$  heuristics present in the network.

$$s_x = \sum_{j=1}^m \alpha_{xj} \quad (3)$$

An example for a system of  $m = 3$  heuristics and  $l = 3$  problems is given in figure 3.

**Network Dynamics** Each iteration, one new heuristic is generated and is made available to the network. The affinity metric described encourages *diversity* between pairs of

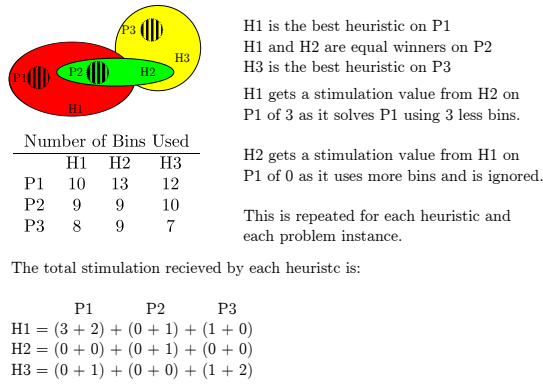

Figure 3: Affinity between Complementary Heuristics

heuristics leading to increased network performance by sustaining those that cover different parts of the problem space. In a practical application however, it is reasonable to assume that in addition to maintaining diversity, important goals of the system should be to find (1) the set of heuristics that most efficiently cover the problem space and (2) the set that collectively minimise the total number of bins used to solve all problems the network is exposed to. While the latter is addressed by sustaining any heuristic with non-zero stimulation, the former goal requires some attention.

Previous AIS models relating to idiotypic networks attempt to use Farmer's original equation (Farmer et al., 1986) to govern the dynamics of addition and removal of nodes from a network. In machine-learning applications such as data-clustering this was quickly found to lead to population explosion e.g. Timmis et al. (2000), later addressed by using resource limiting mechanisms (Timmis and Neal, 2001). In previous robotic applications, the situation is avoided completely by using a network of fixed size and focusing only on evolving connections. In more theoretical models such as Hart (2006) the criteria are not relevant, as the goal is simply to show that a network can be sustained. In this heuristic case, simply sustaining all heuristics that contribute to covering the heuristic space is likely to lead to population explosion in the same manner observed in data-mining applications, as no pressure exists on the system to encourage efficiency.

Therefore, at the end of each iteration, the contribution made by each heuristic to the overall performance is calculated in terms of whether it plays a unique contribution in determining the overall quality of the system. Any heuristic whose contribution is subsumed by one or more other heuristics is removed from the system. Thus, in Figure 3 heuristic  $H2$  is subsumed by the combination of  $H1$  and  $H3$  and is therefore removed from the system. This simple method thus provides pressure on the system to minimise the number of heuristics used. This can be thought of as an artificial form of apoptosis that removes antibodies that

cover duplicate parts of the landscape and allows for proliferation of new cells only in the case that they cover an equal or greater area of the search space that an existing heuristic is occupying.

Pseudo-code describing the network dynamics is given in Algorithm 2.  $\mathcal{H}$  is the set of heuristics currently present in the network,  $\mathcal{E}$  is the set of problems in the current environment. Note that there is a single parameter in the algorithm that defines the maximum concentration a heuristic can reach. This parameter introduces user control over the period of the network *memory* and is discussed in section .

## Experimental Results

A number of experiments were conducted using the model described with the test set of 1370 instances previously described in section .

### Baseline comparison on a static dataset

An initial experiment was performed in order to compare the AIS model to previous work in terms of solution quality on a *static* data set. 1370 instances were split into two sets: the *training* set comprised of the first and then every second problem instance from each of the data sets with the remaining problem instances used as a test set. This split ensured an even distribution of problem instances from each of parameter combinations used to generate them in the test and training set. All 685 problems in the training set were placed in the AIS environment, and the AIS algorithm run for 200 iterations. The quality of the network is measured in terms of the number of problem instances for which the known optimal solution was found by at least one heuristic, and additionally in terms of the number of extra bins

required to solve the instances compared to the known optimal. Results are recorded for problem instances in the training set, and then on the test set of instances (with no further iteration of the network). The experiments are repeated 30 times, reinitialising the system each time. Results are compared to using each of the single deterministic heuristics and to the island model described in Sim and Hart (2013) and shown in table 3a.

The best results shown for the AIS are identical to the best results presented in Sim and Hart (2013), even though the Island Model in that publication required evolutionary operators in order to find solutions and the AIS relies simply on randomly generated heuristics. Given this performance, we now examine the response of the system to dynamically changing data.

### Response to dynamically changing data

The AIS method was inspired by the ability of the natural immune system to rapidly respond to a dynamically changing environment, in which the self-sustaining network of antibodies is postulated to act as a memory of past responses. Four experiments were devised in order to investigate the behaviour of the system under the following dynamically changing conditions.

1. A set of 685 randomly selected problem instances is introduced every 200 iterations. At this point, problems currently in the system are removed, the network cleared, and the system is started from scratch
2. A set of 685 randomly selected problem instances is introduced every 200 iterations. At this point, problems currently in the system are removed, but the existing network is retained
3. Every 200 iterations the problem instances used are toggled between those from Scholl's data sets 1 & 2 (described in Table 1). Antibodies in the existing network are retained.
4. A new problem is introduced every iteration. The existing network is retained.

**Experiment 1** was designed to investigate the time taken for the system to reach equilibrium from an initial starting state. The results are shown in Figure 4. Note that in this graph (and in the following ones) only the first 5 cycles are shown. At the end of each 200 iteration cycle, the total number of bins required by the system is *assumed* to be the best that can be achieved and is given a score of 0. The y-axis then shows the number of bins required over and above this score, enabling different sets of problem instances where the optimal number of bins required varies to be plotted on a relative scale to highlight the response to changing conditions.

It is clear that the system performs poorly at the point of restart requiring up to 1200 extra bins than the best result

Figure 4: Response when the system is completely restarted every 200 iterations

Figure 5: Response When the Problem Instances are Changed every 200 iterations

found during each cycle. The response is still rapid however: the median number of iterations required to reach the best result is 65 (shown in table4 ).

**Experiment 2** examines the role of memory, implicit in the sustained network. The system is effectively trained during a 200 iteration cycle on a set of problem instances representative of the whole set of 1370 problem instances. When the problem instances are changed, the heuristics already in the system have a greater probability of performing well on the new set of problem instances than randomly generated ones due to the shared problem characteristics. Results are shown in Figure 5. The median number of iterations to reach the optimal value is 10 and the total number of bins required is at most 5 greater than that at the end point (Table 4).

**Experiment 3** presents a more difficult test for the system; the two alternating problem sets have very different characteristics. The memory encapsulated in the network is therefore expected to be of less relevance. Results are shown in Figure 6 and in Table 4. Performance drops in comparison to Figure 5 where the memory could be exploited; however, there is still an improvement in comparison to the complete re-start applied in Experiment 1.

Finally, **Experiment 4** investigates the system response to slowly changing environmental conditions. Figure 7 shows how the system responds as problem instances are gradually introduced to the system. The system starts with no problem instances and no heuristics. Each iteration one randomly

generated heuristic and one randomly selected problem instance are introduced. The graph shows the percentage of extra bins over the known optimal that are required using the heuristics present in the network at each iteration. The number of heuristics sustained by the system is also shown.

Most benefit is gained from adding new heuristics when few heuristics are present. As the number of heuristics increases, it becomes harder for a newly added heuristic to

find a new niche. Furthermore, the total number of potential heuristics is limited by the generation method currently used (although this could easily be extended by adding new nodes).

## Conclusion

We have introduced an AIS model for generating and maintaining a repertoire of heuristics that solve bin-packing problems. Results show that the model achieves equal results to state-of-the-art methods on static data sets, and is extremely responsive to dynamically changing data-sets, making it suitable for use as a continuous learning system. The memory encapsulated in the network can be exploited to provide a rapid response to new problems that share characteristics with those previously seen by the network.

The model can be generalised to other domains by replacing the component parts of the heuristic generator. Currently, the generation model does not make use of any evolutionary or cloning operators to improve randomly generated solutions. By adding this feature in the future, it is hoped to speed up the response even further.

## Abstract

We describe an immune inspired approach to achieve self-expression within an ensemble, i.e. enabling an ensemble of autonomic components to dynamically change their coordination pattern during the runtime execution of a given task. Building on previous work using idiotypic networks, we consider robotic swarms in which each robot has a lymph node containing a set of antibodies describing conditions under which different coordination patterns can be applied. Antibodies are shared between robots that come into communication range facilitating collaboration. Tests in simulation in robotic arenas of varying complexity show that the swarm is able to learn suitable patterns and effectively achieve a foraging task, particularly in arenas of high complexity.

## Introduction

Current and emerging ICT scenarios increasingly rely on complex distributed software systems in order to function properly in dynamic and unpredictable environments Zambonelli et al. (2011). This results in a need for the software controlling such systems to become *autonomic* in adapting behaviours such that quality of service of the system is maintained.

In Zambonelli et al. (2011), the authors describe two important dimensions of adaptation that can occur within autonomic systems, which they refer to as *where* and *what*. *Where* relates to where adaptation takes place, i.e. at the individual or ensemble level. *What* on the other hand refers to the set of mechanisms the system can utilise to adapt. They distinguish between *self-adaptation* and *self-expression*: the former refers to components or ensembles modifying their parameters so as to exploit their current abilities, whereas the latter describes the ability of radically modifying at run-time the structure of components and ensembles. In terms of ensembles, self-expression could result in re-structuring in terms of topology (e.g., switching from a hierarchy to a collective of peers) or of control regime for interactions (e.g., switching from being a collective decision-making ensemble to a competitive market-based one) Zambonelli et al. (2011).

While self-adaptation mechanisms at both individual and ensemble levels has been the focus of much research (e.g.

see Salehie and Tahvildari (2009) for overviews), mechanisms for achieving self-expression in distributed systems are less well-understood, particularly with respect to systems that enable software within an ensemble to express at run-time the most useful interaction topology or control regime. Inspired by the fact the features and properties apparent in the natural immune system such as scalability, adaptivity through learning and decentralization map naturally to those desired in autonomic systems Cabri and Capodieci (2013), we describe an idiotypic-network approach to self-expression. We consider a swarm-robotic scenario in which multiple robots have to fulfil a simple foraging task. Multiple *coordination patterns*, i.e. collaborative strategies, are available to the robots to face the problem; robots contains a lymph node describing a set of antibodies that indicate a suitable strategy — by sharing of antibodies across the swarm when robots come into contact with each other, the entire swarm is able to learn to solve the problem over time, even when placed in environments of varying complexity.

## Previous Work

A fruitful line of work within robotics that started with Ishiguro et al. (1995) has applied inspiration from Jerne's idiotypic network theory to develop behaviour arbitration mechanisms in individual robots. Antibodies consist of a matching condition to match environmental conditions, an action, and of receptors that enable interactions with other antibodies. The resulting network of stimulatory and suppressive connections alters concentrations of antibodies; the one with the highest concentration applies its action. Various weaknesses in this work that required hand-coding of antibodies for instance have recently been addressed in Whitbrook et al. (2010b), who consider evolutionary methods for generating antibodies and reinforcement learning to connecting them in a network, resulting in a system that has been ported successfully to real-robots Whitbrook et al. (2010a). We extend this work in that we deal with *swarms* of robots rather than individuals, and that rather than considering individual actions, the robots must select a cooperative strategy to take

Figure 1: A footbot. Sensors and actuators are placed as follows: (1) omni-directional sensing camera, (2) proximity sensors, (3) LEDs, (4,5) wheels and ground sensors, (6) RAB sensor and actuator

Figure 2: Simple example arena. Footbots in action are shown, together with the blue light symbolizing the nest and, in the opposite end, a red light for indicating the food area.

part in.

There have also been previous attempts to apply idiotypic network ideas to swarms. In Jun et al. (1999), a distributed version of Ishiguro et al. (1995) is proposed, in which individual robots choose an appropriate action according to a changing environment and the experiences of nearby robots. In Luh et al. (2006), instead of a single action, more complex behaviours are selected as a result of modelling a two layered immune network, merged as interaction among antibodies in the single robot and then distributed throughout all the swarm. Our work differs from both these publications, firstly in the robotic scenarios used and for switching *coordination patterns* as a response of the designed artificial immune network; this implies not only selecting behaviours, but also roles, statuses and interactions within the coordination pattern, and can result in dynamically changing interacting topologies, e.g. switching from a peer-to-peer coordination pattern to a purely stigmergic communicative collaborative effort and vice-versa.

## Task and robot description

We model a simple task in which a swarm of robots, initially randomly distributed in a confined arena, are required to collect food from a source and return that food to a nest, in an iterative process. The goal of the task is to maximise the total amount of food returned to the nest in a fixed time period, although performance can also be evaluated in terms of the rate of food collection over shorter time periods. The robot used in the simulation is called a *footbot*, and is one of the types of robot used in the swarmanoid project Dorigo et al. (2012) and in other previous research regarding swarm robotics coordination, e.g. Capodiceci and Cabri (2013) — see Figure 1. The sensors and actuators used on the robot are relatively simple. For instance, each robot is not able to calculate its position in space, nor does it have any concept of orientation. The modelled sensors and actuators are shown in table 1.

## Coordination Patterns

Three coordination patterns are considered: a completely swarm approach, a peer-to-peer (p2p) directly communicative approach and a baseline coordination strategy operated with the limited amount of sensors and actuators. The artificial immune system (AIS) enables the robots to select between these patterns based on their assessment of the complexity of their current environment and expected utility.

## RACO: Robotic Ant Colony Optimization

*RACO* is a robotic application of the well-known ant colony optimization family of algorithms Dorigo et al. (1996). In a typical ACO implementation a virtual pheromone trail is used to guide agents towards an object of interest; in a robotic scenario, as it is difficult for a robot to actively modify the environment by laying pheromones, some of the robots in the swarm adopt the role of pheromone: each robot

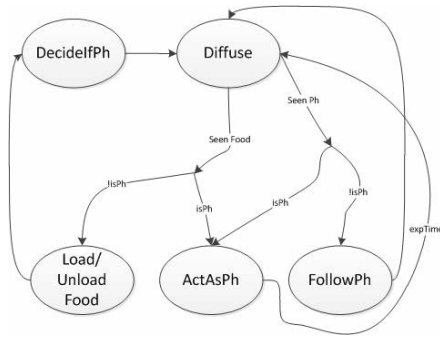

Figure 3: States and conditions for the RACO algorithm

is assigned a (small) probability  $p$  of acting a pheromone, with the remaining  $(1 - p)$  act as ants. All the robots start by uniformly diffusing into the area following a very simple diffusive algorithm: each robot starts with a random orientation and starts moving in a straight line; if a collision is sensed in one or more of the 24 proximity sensors the robot reacts by moving in the opposite direction from the sensed collision. If a robot that has decided to act as a *pheromone* reaches the food area (represented by a red emitting light) or the nest area (blue light), the robot stops moving and lights all 12 of its LEDs in yellow. Robots from the *ants* group continue to diffuse uniformly until they sense a pheromone; at this point they follow the pheromone trail rather than diffuse uniformly. The *intensity* of the pheromone is represented by the brightness of the emitted light. The more intense the light, the greater the distance from which it can be perceived by other robots. Intensity decays according to equation 1 which models evaporation over time (also shown in Figure 4).

$$Intensity(t) = MaxIntensity - \left( \frac{\beta e^{\frac{6t}{expTime}}}{1 - (\alpha - \beta)} + e^{(\alpha - \beta)(\frac{6t}{expTime})} \right) \quad (1)$$

In eq. 1,  $MaxIntensity$  represents the maximum value for the light intensity emitted by the robot's LEDs.  $expTime$  is the maximum expiration time (when the intensity reaches zero),  $t$  is the time variable and  $\alpha$  and  $\beta$  are constants. When the expiration time of the pheromone reaches zero, the *pheromone* robot switches its role to become an *ant* robot once more. However, if an *ant* robot comes within a distance  $d$  of the pheromone, the pheromone regenerates and its value is reset to  $MaxIntensity$ . When the expiration time of the pheromone reaches zero, the pheromone robot switches its role to become an ant robot (see Figure 3). Every robot makes its decision to act as a pheromone every time the food or nest area is reached, and that's how new pheromones are created.

Figure 4: Exponential evaporation time for the pheromone robot: emitted light intensity  $A$  over time

### AMORPH: Amorphous computing inspired path formation

The second coordination pattern strongly relies on communications in the form of packets sent and received with the RAB sensor and actuator built in each robot. This is purely peer-to-peer (p2p) approach in which roles are assigned dynamically according to the current situation. This strategy is inspired by the work of *Abelson et al.* in Abelson et al. (2000) which studies the use of bio-inspired algorithms for achieving collaboration among a potentially large number of devices connected in unknown way. The algorithm is described in detail in Abelson et al. (2000); the modifications required to adapt this to a robotic swarm are discussed below. Its underlying concept is to diffuse a gradient across the amorphous net of communicating robots indicating the shortest path from the nest to the food source.

The swarm starts by contracting who will be the path opener: any robot sensing the nest area (blue light) sends a message to nearby robots indicating its distance from the light. Any robot receiving a distance greater than the one it currently holds begins to diffuse; the process results in the single robot that is furthest from the light becoming the path-opener and remains stationary (robot A in figure 5). Robots diffuse uniformly until one robot reaches the nest area (red light) at which point it becomes the *path-closer* (robot-F in figure 5) and halts. This robot sends out a packet to nearby robots via infra-red signalling through the RAB actuator) consisting of the tuple (*SenderID*, *gradient*, *state*, *successorID*). *Gradient* is an indicator of the distance to the start of the path, *state* is a boolean value indicating whether a robot is currently part of the path, *successorID* is the ID of the robot that previously sent the highest gradient value to the receiving robot. The path-closer sends the maximum gradient value (255). Receiving robots store the highest value received  $g$ . They then transmit a new gradient  $g - 1$ . The chain ends when the *path-opener* receives a gradient and transmits

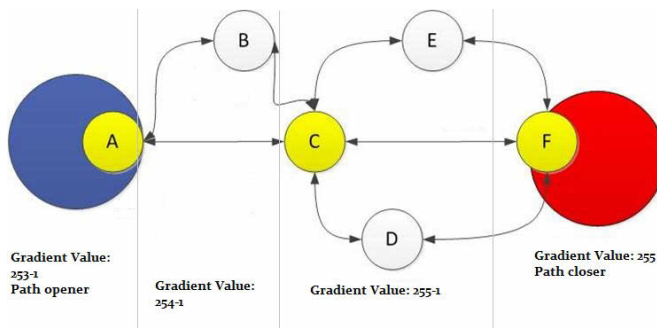

Figure 5: Schematic of an example situation in the amorphous path formation algorithm: communication is variable due to random placement, obstacles and limited RAB range for signalling. A possible communication topology is shown by the lines and arrows. At the end of the algorithm, robots A,C,F provide the path from food to nest area.

a message that a path is ready to be formed (setting the *state* packet to 1). All robots (including the *path-opener*) receiving state 1 set their LEDS to a specific colour thus indicating the path. Robots not on the path now follow the lit path to the food.

An emergent property of this algorithm is that the path of lit robots formed is exactly one-robot thick. The robots that are inside this path will be referred as *nodes*, while the other robots can still be called ant robots since their behaviour now is very similar to the one described in the previous coordination pattern.

### Baseline strategy: blind diffusion

An additional cooperative strategy is represented by a coordination pattern that uses the minimum amount of sensors and actuators. It is called blind diffusion, since all the robots are *blind*, in the sense that they disable the omni-directional camera, thus are unable to sense lights and colour for being attracted towards the point of interests in the arena.

All robots apply a simple diffusion algorithm: when a collision is sensed through the proximity sensor, they steer in opposite direction by rotating in a direction opposite to the angle to incidence w.r.t. their body centre of the proximity sensor detecting the collision. An emergent property of this algorithm is that the swarm becomes uniformly distributed throughout the whole arena. In this algorithm, food is sensed by ground sensors built in the wheels of each robot that detect floor colours based on a grey-scale. However, it should be clear that this algorithm will be much less effective than the previous approaches in terms of the amount of food collected.

### Remarks on coordination pattern performance

Previous experimentations with each of three coordination patterns in a small area led to a number of observations

Figure 6: lymph-nodes are robots with variable connectivity and they can host a multitude of interconnected antibodies.

that motivates the selection strategy introduced in this paper. Briefly, it was observed that the AMORPH algorithm performs best (in terms of total food collected) in complex arenas, where complexity relates to both the size of the arena and the number of obstacles present. In simple (obstacle free) arenas, RACO performs best — probably due to the fact the the RACO algorithm enables more robots to be devoted to foraging, rather than being tied up in path construction. Both algorithms struggle in some situations as both lack a proper obstacle avoidance behaviour, therefore certain configurations of either node or pheromone robots can impede performance. This motivates the algorithm presented, which is not only able to dynamically alter the current coordination pattern due to online feedback regarding current performance, but also results in subsets of the swarm in fact following different coordination patterns at any given moment. This is described in the next section.

### SelfEx - Model

The model introduced extends work originally discussed in Ishiguro et al. (1995). Significantly, we extend the concept of controlling an individual robot through a network of antibodies that match conditions to actions to a distributed swarm in which the robots only have limited communication range. Each robot is modelled as a lymph node that contains a set of antibodies, connected in an idiotypic network, see Figure 6. Robots can diffuse antibodies from one lymph node to another, thus the contents of lymph nodes are continually adapted. In contrast to previous work, antibodies determine the *coordination pattern* that should be executed by the robot at a given moment rather than a specific action. The algorithm (**SelfEx**) is given in listing 1 and is described in detail below.

As we can see in fig. 6 each robot is modelled as a lymph-node in a net of lymph-nodes whose connectivity varies according to the ever changing position of the robots. By taking a look inside each robot, we can see how each lymph-node can host a multitude of interconnected antibodies and each antibody is characterized by a variable concentration value and it is divided into three main parts that will be ex-

plained in the following section.

---

**Algorithm 1** SelfEx: overview
 

---

- 1: **Initialisation**: each robot initialised with a set of antibodies
  - 2: **Maturation**: each robot estimates the complexity of the environment
  - 3: **Selection**: each robot selects a start coordination pattern based on its antibody that highest affinity with the environment
  - 4: **repeat**
  - 5:   **Evaluation & Affinity Update**: every *eval* timesteps, each robot evaluates its performance and updates the affinities between antibodies in its own idiotypic network
  - 6:   **Concentration Update**: each robot updates the concentration of each antibody within its lymph node
  - 7:   **Diffusion**: the best antibodies are diffused to robots within communication range
  - 8: **until** stopping criteria
- 

**Antibodies and Affinity** An antibody is a tuple of values  $\langle \text{Conditions}, \text{Action}, \text{expected utilities} \rangle$  as follows:

- **Condition** has two variables, *complexity* and *status*. *Complexity* is a real-value representing the complexity of the arena. *Status*  $\in \{0, 1, t\}$  where 0 indicates an ant robot in the RACO model, 1 a node robot in the AMORPH model and *t* indicates the time a robot has spent in the pheromone state in the case of pheromone robots.
- **Action**  $\in \langle \text{BlindDiffusion}, \text{RACO}, \text{AMORPH} \rangle$ .
- **Utility** is the value of the food collected in a time period, *eval* by each robot

The *affinity* between an antibody and the current environment is calculated as the Manhattan distance between the calculated *complexity* and the *complexity* value stored in the antibody.

**Initialisation** A set of antibodies to seed networks were derived from an initialisation phase; during this phase, a swarm utilised each individual coordination pattern in each tested arena over a 50000 time-step period. During this period, each robot logged its status, perceived complexity index and the amount of food it managed to collect during the evaluation time. These results were then averaged to build an initial set of 10 seed antibodies. Each robot's lymph node is loaded with the same set of 10 antibodies found. The initial concentration of each antibody in each lymph node is set to zero.

**Maturation** The purpose of the maturation phase is for each robot to estimate the complexity of the environment. This is calculated according to algorithm 2. Note that the lower the value of *complexity* calculated, the higher the complexity of the arena.

---

**Algorithm 2** SelfEx: Maturation Phase
 

---

- 1: initialise lymph node of each robot with a set of antibodies
  - 2: Goal  $\in \{Food, Nest\}$
  - 3: **repeat**
  - 4:   **for all** robot *i* in  $\mathcal{R}$  **do**
  - 5:     Move according to *blind diffusion pattern*
  - 6:     **if** Goal encountered **then**
  - 7:       *maturationCounter*<sub>*i*</sub>  $\leftarrow$  *maturationCounter* + 1
  - 8:     **end if**
  - 9:   **end for**
  - 10: **until** end of maturation phase
  - 11: *complexity* = averaged value of each robots *maturationCounter*
- 

**Evaluation and Affinity Update** After *eval* timesteps, each robot evaluates its own performance *u* and compares this to the expected utility *u<sub>E</sub>* indicated in the currently active antibody. If  $u > u_E$  then positive feedback is given to the selected antibody by increasing the affinities from all other antibodies towards the selected one; in addition to that, the expected utility field of this antibody is updated with the newly obtained value. If  $u < u_E$  then negative feedback results in the the selected antibody increasing its affinity to all other antibodies. Affinity values *r* (between antibody *i* and *j*) are calculated as follows:

$$r_{i,j} = \omega |obtUtilities - expUtilities| + \frac{K_0}{|dAc - abAc|}$$

$$\omega = \begin{cases} status & \text{if } status \leq 1 \\ 1 - \frac{status}{evalTime} & \text{if } status > 1 \end{cases} \quad (2)$$

The difference between obtained utilities (*obtUtilities*) and expected utilities (*expUtilities*) is weighted according to the *status* variables (see section ). In addition, the affinity is adjusted according to the difference in the detected area complexity and the complexity value stored in the antibody, regulated by the constant  $K_0$  ( $< 1$ ).

**Concentration Update** Antibody concentration updates are performed in a similar manner to that of Ishiguro et al. (1995) as shown in eq. 3. The main differences are that we assume that every antibody is connected to all the other antibodies, antibodies with low concentration are not removed, and we do not add new antibodies.

$$\frac{dc_i}{dt} = K_1 \sum_{j=0}^N r_{j,i} c_i c_j - K_2 \sum_{k=0}^N r_{i,k} c_i c_k + K_3 D c_i \quad (3)$$

The first term of eq. 3 refers to the stimulation part of the immune net; the second term (with a negative sign) refers to the suppression operated by the other antibodies and the latter term takes into account the euclidean distance  $D$  among all the conditions of the antibodies to the obtained/detected values of status, utilities and area complexity. Three constants ( $K_{1,2,3}$ ) regulates the contribution of each of these effects. The resulting concentration is then squashed to fit the  $[1...255]$  range.

**Diffusion** The calculated concentrations of the four antibodies with highest concentration in each lymph node are now shared amongst other robots in range, in order to distribute knowledge throughout the ensemble regarding current performance in a single packet<sup>1</sup>.

*Ant* robots *broadcast* such packets but do not *receive* packets as they are able to form their own estimate of how much food has been collected. *Pheromone* and *Node* robots average its concentration with the external concentration sent by other robots for each antibody. Following the updating step, the robot selects the antibody with the highest concentration and executes the coordination pattern indicated.

## Experiments and simulations

The pre-experimentation phase to establish the initial set of antibodies was undertaken in two areas; the first was characterized by the highest complexity index (visible in fig. 2, the simplest area), while the second arena with a high-index used an extensive sized hexagonal arena with an obstacle between the straight path from nest to food area. Tests with the main algorithm were performed in three different arenas: the two described above and one of intermediate complexity. Each experiment was repeated 10 times, with a different random initial distribution of robots each time. In each arena, experiments were performed with the single RACO and AMORPH algorithms as well as with SelfEx. Parameters were tuned through an empirical process — values used in the results reported are shown in table 2. The experiments were performed using *ARGoS* swarm robotics simulator (Pinciroli et al. (2012)).

## Results and remarks

As stated previously, the experiments were evaluated on the basis of total performances over the total length of the experiment and the variation of food collected each evaluation period (by the entire swarm). This latter metric is useful to note the gradual improvements of each collaborative effort:

<sup>1</sup>Only four antibodies are distributed due to the limitations of the RAB sensor

| Parameter | Description                         | Value   |
|-----------|-------------------------------------|---------|
| eval      | evaluation period for affinity step | 10,000  |
| l         | total timesteps experiment run      | 200,000 |
| m         | maturation phase length             | 5500    |
| $K_0$     | from equation 2                     | 0.05    |
| $K_1$     | from equation 3                     | 0.25    |
| $K_2$     | from equation 3                     | 1       |
| $K_3$     | from equation 3                     | 0.05    |
| $p$       | probability to become a pheromone   | 0.35    |
| $expTime$ | from equation 1 (RACO)              | 1500    |
| $\alpha$  | from equation 1 (RACO)              | 0.3     |
| $\beta$   | from equation 1 (RACO)              | 0.8     |

Table 2: Values of parameters used for the simulations

the AIS approach should show an average increasing trend in the amount of food collected in each time interval, in order to indicate the network is *learning*. Figure 7 shows the results of the simplest arena. SelfEx and RACO have similar performance, although SelfEx is less variable than RACO. AMORPH performs best in terms of the median value of food collected and variability. However it is clear from the right hand figure that the performance of AMORPH deteriorates over time, whereas SelfEx and RACO show steady improvement, suggesting that given further time they may at least equal the AMORPH performance. In the second arena (Figure 8) RACO performs best. SelfEx performs better than AMORPH, particularly in terms of variability. As in the first arena, the performance of SelfEx increases over time, a pattern not clear in RACO and AMORPH. Finally, in the third and most difficult arena, the best performance is achieved by SelfEx (Figure 9). In this arena, performance does not increase over time, suggesting the ensemble reached consensus on the coordination pattern to adopt very early in the experiment.

Figure 10 shows the percentage of robots in each evaluation period that follow the different coordination patterns in Arenas 1 and 3 (figures from a single run). In Arena 1, the swarm is divided in its choice of pattern — interestingly, some robots still select the blind diffusion strategy. In contrast, in Arena 3, robots eventually converge towards a single coordination pattern. The ability of SelfEx to enable heterogeneous behaviours might be particularly useful in more dynamic environments.

## Conclusions and Future Work

We have introduced a novel approach to managing a collaborative swarm of robots by taking inspiration both from autonomic computing and bio-inspired algorithms, and extending previous work that used idiotypic network models to control individual robots. The model was tested on a simple foraging task in which robots had to choose a coordination pattern from a set of three different possibilities. Each robot

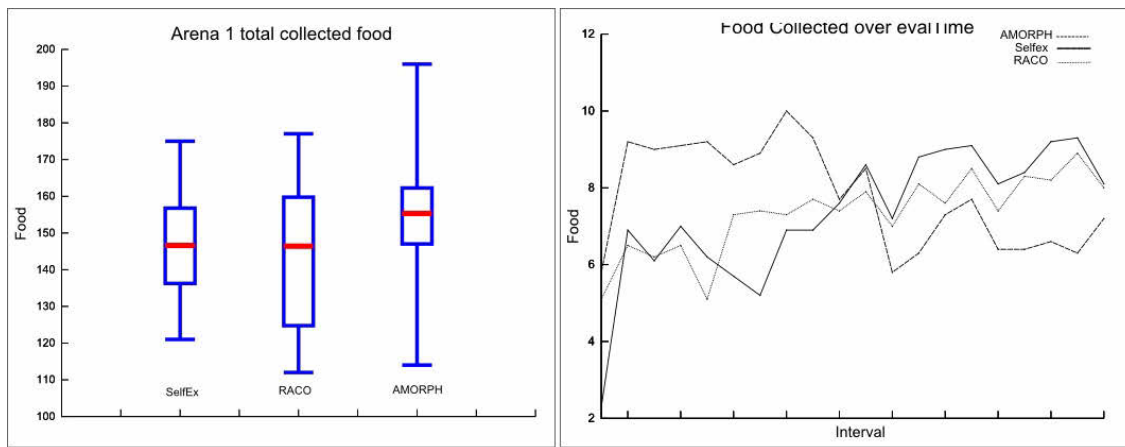

Figure 7: First test arena results

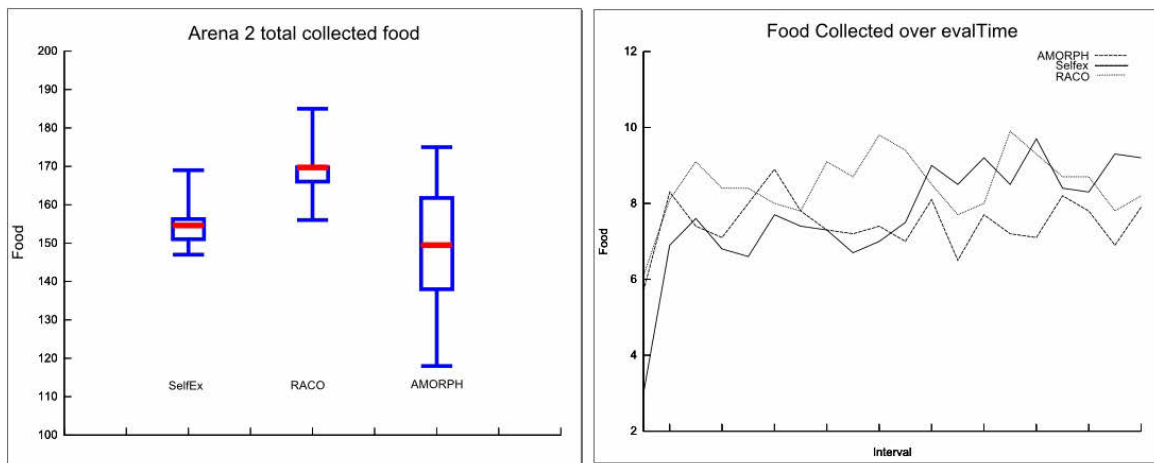

Figure 8: Second test arena results

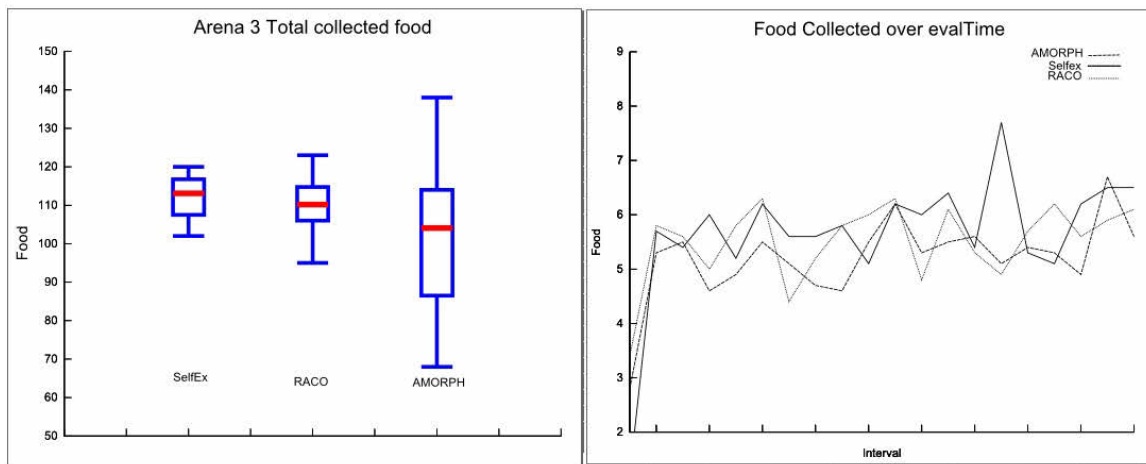

Figure 9: Third test arena results

Figure 10: Distribution of coordination patterns amongst robots in each time interval. The top figure shows Arena 1, the lower Arena 3. The figures are 'stacked' in the order blind diffusion, RACO, AMORPH from the bottom

is a modelled as lymph node hosting a connected network of antibodies. Sharing of antibodies across robots enables common decisions to be made as to the best manner to fulfill the task. The results shown that the ensemble was able to deploy Self-Expression, i.e. fragmenting into sub-sets and initially choosing different coordination pattern. The results show that the SelfEx approach was able to learn and improve its performance over time, thus demonstrating the cognitive ability as emerging property of an immune net. However, the overall performances also show that how our approach is slow to converge and the maturation phase implies smaller quantities of collected food during the initial time intervals: there is a large room for improvements by appropriately tuning the parameters involved. Additional improvement could be gained by using a hyper-mutation process in order to optimise individual antibodies within a network via a local search process.

## Abstract

In the research of multi-objective optimization algorithm, evolutionary algorithms have considered to be very successful tools. Artificial Immune System (AIS)-based algorithms as one of the viable alternative have also be widely developed in this domain. Over the years, researchers of evolutionary algorithms have extended their interest to many-objective situations; however works in AIS-based algorithms is rather scattered. This paper extends an AIS-based optimization algorithm to solve such many-objective optimization problems. The idea of  $\varepsilon$ -dominance and the holistic model of the immune network theory have been adopted to enhance the exploitation ability aiming for a quick convergence.

## AIS-based Many-objective Optimization Algorithm

Evolutionary algorithms (MOEA) have shown to be the state-of-art tools for solving multi-objective optimization problems with 2 or 3 objectives. The application has been extended to many-objective situation with 4 or more objectives. With modification in the fitness assignment process and the evolution scheme, these algorithms achieve satisfactory results.

AIS-based algorithms are considered to be one of the viable alternatives in multi-objective optimization. A number of AIS-based multi-objective optimization algorithms have been proposed with promising results (Shang, 2012; Tsang and Lau, 2012). Majority of these studies focus on 2 to 3 objectives, with many-objective situations rarely being considered. The experiment in (Jarosz and Burczynski, 2011) had extended the application to 5 objectives. However, the study of many-objective optimization with AIS is still rare. This study therefore attempts to develop a novel AIS-based algorithm for solving many-objective problems.

In general, an AIS-based multi-objective optimization algorithm first generates the initial population. This population will go through cloning, variation, evaluation, network suppression and memory updating. Cloning and variation process generates modified solutions. Evaluation process assesses the fitness of each solution. Different fitness assignment scheme was proposed to increase the chance of domination.  $\varepsilon$ -dominance is one of them which relaxes the dominance requirement (Hernández-Díaz, et al. 2007). The resulting solutions are often dominated by solutions with

lower or equal fitness in all objectives which are close enough to non-dominated solutions. Memory updating process selects population for next generation.

Inspired by the immune network theory, network suppression process provides a means to manage diversity. Such operation differentiates the AIS-based approaches from evolutionary algorithms in optimization. 'Near' solutions are suppressed to reduce redundant search. The concept of network interaction with suppression and activation had been implemented and tested on multi-objective optimization with promising results (Tsang and Lau, 2010). This study builds on the success in past studies and extends to many-objective situations. When a solution suppresses and dominates near solutions, this suppression hints a potential promising search if the exploitation can go further in the same direction from the dominated solution to the non-dominated solution. This suppression triggers the activation through generating new solutions on the identified high-potential space. The difference in decision variables define the search area and step size. New solutions will be generated based on the direction and step size as defined. Such an approach can supplement the dominance relation in identifying the searching area which accelerates the convergence through directed exploitation.

## Experiment and Conclusion

The AIS-based approach enhanced with the proposed network activation scheme has been implemented and compared against the general AIS-based approach and some other conventional approaches. Test problems from the DTLZ family (Deb, et al. 2002), which are scalable to different number of objectives, are used for studying the performance in continuous functions.

Preliminary results comparing with the NSGA-II (Deb, et al. 2000) and using the Coverage C metrics (Zitzler, 1999) are shown.  $C(A,B)$  gives the proportion of solutions in B that are dominated by solutions in A.  $C(\text{AIS}, \text{NSGA-II})$  is much higher than  $C(\text{NSGA-II}, \text{AIS})$  for all 3 cases of increasing number of objectives. Box-plot is used as the presentation tools as it displays also the summary of the whole result including the outliers. The results show the potential of the AIS-based many-objective optimization algorithm.

\*mark.read@york.ac.uk

The emerging field of computational immunology shows great promise to advance immunological research. Simulations of immunological systems provide a platform for *in silico* experimentation, facilitating the formulation and evaluation of hypotheses.

A major challenge in this field, however, lies in parameterization, particularly in agent-based simulations. These simulations contain many parameters (>50 is plausible), many pertaining to aspects of immunology that either have not or cannot be examined with current wet-lab technologies. Curve-fitting (e.g. linear regression) based-calibration is tractable only for relatively simple simulations with few parameters, and will not necessarily lead to biologically-plausible parameter values (e.g., if the model is a bad representation of the biology). For larger systems the current state of the art is to calibrate by hand/eye, with some values based on wet-lab data or expert opinion, and the rest on trial and error. Furthermore, it is typical to calibrate simulations against data from only a single wet-lab experiment. Although these data may comprise observations of multiple cells/molecules/disease scores (termed *responses*), given that a simulation is likely to be used to perform *multiple* novel experiments that have not been attempted in the wet-lab, it still constitutes calibration against a single data-point (single experiment). Put another way, with so many degrees of freedom there may be multiple points in parameter space for which a simulation re-creates data from a single experiment; a simulation calibrated in such a manner will not necessarily be representative of the biology when used for a different experiment. We propose that to have genuine trust that they reliably capture the biology, immunological simulations should be calibrated against multiple wet-lab experiments.

Performing calibration of this magnitude by hand is intractable, and as such we are investigating alternatives based on automated multi-objective meta-heuristic search techniques. Each wet-lab experiment used in calibration is performed also in simulation. Each response from each experiment is treated as an individual objective that the search algorithm must align simulation behaviour with. The

search algorithm searches for parameter values that satisfy all these constraints. We are developing this methodology by calibrating ARTIMMUS, an existing simulation of the murine autoimmune disease Experimental Autoimmune Encephalomyelitis (Read, 2011), using NSGA-II (K Deb, 2002), a multi-objective search technique. ARTIMMUS hand-calibrated parameters have been shown to reflect the *in vivo* disease dynamics of EAE (Read, 2011; Mark Read, 2012). ARTIMMUS comprises around 70 parameters, representing a very large search space. In demonstrating proof of principle of this technique we first calibrate a restricted set of 8 key parameters (shown in figure 1c; all other parameters retain their previously calibrated values, see Read (2011)), gradually increasing the range of permitted values over which the search process may operate, and the number of objectives.

Results are promising: figure 1a depicts previously calibrated simulation behaviour (left), and NSGA-II's best attempt at recreating it (right) (Tripp, 2013). The absolute difference between target (hand-calibrated) values and those obtained by NSGA-II are shown in figure 1b. This experiment represents the most difficult problem setup that was attempted. NSGA-II operated on 6 objectives, attempting to match the peak numbers of CD4Th1, CD4Treg, CD8Treg, the times at which these peaks occurred for CD4Th1 and CD8Treg, and the number of CD4Th1 cells remaining at 40 days. The difficulty of this search problem must be emphasized, the 8 parameters being calibrated constitutes a substantial search space, and 6 objectives is a lot for a multi-objective optimization algorithm such as this. Nonetheless, the results are promising and further investigation, in particular incorporating dynamics from a second experiment, is warranted. Interestingly, the search process highlighted how disparate areas of search space could provide seemingly well-aligned behaviours (termed *local optima*) when calibrating against this one experiment. This highlights the importance of more powerful calibration techniques: the existence of multiple local optima in immunological simulations when calibrating against single experiments is problematic for reasons outlined above. Furthermore, if state-of-

(c) The parameters over which NSGA-II performs optimization. Hand calibrated and NSGA-II parameter values are given, as are the ranges of values over which NSGA-II operated. The best solution found is labelled 'NSGA-II'. DC, dendritic cells; LN, lymph node; CNS, central nervous system. A sub-optimal, but good, result from NSGA-II (labelled 'NSGA-LA') is also given. Fitnesses are shown in parentheses, and represent the sum of absolute differences between hand calibrated and NSGA-optimised response values. Lower fitnesses represent better solutions.

Figure 1: The result from NSGA-II that most closely calibrated ARTIMMUS parameter values against the hand-calibrated target values.

the-art automated methods with access to considerable computational power are challenged by this calibration problem, then those calibrating by eye and hand with trial and error ought to be cautious.

## Abstract

Immunological algorithms are a kind of bio-inspired intelligence methods which draw inspiration from natural immune systems. The problem-solving performance of immunological algorithms mainly lies on the utilization of learning (i.e. mutation) operators. In this paper, nine different learning operators in a standard immune algorithmic framework are investigated. These learning operators consist of eight existing operators and a newly proposed search direction based operator. Experiments are conducted based on nine variants of immunological algorithms that use different learning operators. Simulation results on a large number of benchmark optimization problems give a deep insight into the characteristics of these operators, and further verify that the proposed new learning operator can greatly improve the performance of immunological algorithms.

## Introduction

Many difficulties such as dimensionality, differentiability and multimodality are associated with the optimization of large scale problems. To address such problems, bio-inspired intelligence algorithms (Da Silva Santos et al., 2010; Gao, 2012) have attracted more and more interest, among which the immunological algorithm (IA) is a particular class of optimization methods inspired by the basic features of adaptive immune response to antigenic stimulus. Most IAs mimic the metaphors of clonal selection principle (de Castro and Zuben, 2002), hypermutation (Freitas and Timmis, 2007), receptor editing (Gao et al., 2007) and lateral interaction effect (Whitbrook et al., 2007), providing a promising search mechanism by exploiting and exploring the solution space in parallel and effectively (Dasgupta et al., 2011). The main unique property of IAs is the utilization of the clonal proliferation, and the clonal selection which returns promising solutions acquired in the learning process. It is evident that IAs possess good features of maintaining population diversity, and capability of allocating multiple optimal solutions (Haktanirlar Ulutas and Kulturel-Konak, 2011). Although IAs have achieved good performance in solving various kinds of practical problems, such as digital signal processor (Mitra and Venayagamoorthy, 2010),

nonlinear classification (Ozsen et al., 2009), fault diagnosis (Hao and Sun, 2007), etc, their performance is limited in solving optimization problems (McEwan and Hart, 2009). Compared with other bio-inspired algorithms, such as the well-known evolutionary computation (Yao and Xu, 2006), IAs still greatly suffer from the issues of stagnation and slow convergence. The reason seems to be that the learning capacity (involving hypermutation and receptor editing) has not been fully exploited, i.e., no sophisticated learning operator can be found in the literature (Jansen and Zarges, 2011). Based on the above consideration, we review and analyze the existing learning operators commonly used in IAs, and propose a new search direction based learning operator ( $L_{sd}$ ) to encourage the antibodies to utilize the information of its surrounding antibodies, by means of moving the antibody toward the nearby antibodies with higher affinities and meanwhile away from the antibody with lower affinities. Therefore, the  $L_{sd}$  operator can not only evolve antibodies into promising search areas to accelerate convergence speed, but also prevent antibodies from entering undesired regions to jump out of local optimal solutions. The experiments of using all learning operators in IAs are conducted based on a large number of benchmark numerical optimization problems. The results show the characteristics of each learning operator, and further indicate that the proposed  $L_{sd}$  operator manipulates the best performance.

## Immunological algorithm

To investigate the effect of learning operators, a standard immunological algorithm framework (called IA) is utilized (de Castro and Zuben, 2002; Kelsey and Timmis, 2003). IA evolves a population of antibodies (B cells) towards a global optimum through a process of evaluation, cloning, learning (i.e. mutation) and selection. The evaluation procedure computes the affinity function values for all antibodies. Affinity is an important measure to represent the fitness of antibody to antigen. For a minimization optimization problem, higher affinity values of antibodies correspond to better solutions for the problem needed to be solved. The cloning proliferation is a mitotic procedure whereby the cells divide

themselves, creating a set of clones identical to the parent cell. Generally, the proliferation rate is directly proportional to the affinity level. The learning procedure (involving hypermutation or receptor editing) performs the exploration and exploitation within solution search space, guiding antibodies to the global optimum. It plays a key effect on the search performance of the algorithm. The selection procedure picks up the antibodies with higher affinities and meanwhile eliminates those with lower affinities to reduce the computational complexity.

From the perspective of optimization, a learning operator  $L$  mutate a candidate solution  $Ab = (x_1, x_2, \dots, x_D)$  to a trial one  $Ab' = L(Ab) = (x'_1, x'_2, \dots, x'_D)$ , where  $D$  is the dimension of the problem. In the literature, there are several learning operators commonly used in IA. They are summarized in the following.

- Gaussian mutation  $L_{gs}$  (Yao et al., 1999; de Castro and Timmis, 2002; Xu and Zhang, 2007; Khilwani et al., 2008; Song et al., 2006; Woldemariam and Yen, 2010):  $Ab' = Ab + \alpha N(0, 1)$ , where  $N(0, 1)$  is a random Gaussian number generated by the Gaussian function given as  $f_{Gaussian}(x) = \frac{1}{\sqrt{2\pi}} e^{-\frac{x^2}{2}}$ , and  $\alpha$  controls the learning intensity imposed on the antibodies.
- Cauchy mutation  $L_{cy}$  (Yao et al., 1999; Xu and Zhang, 2007; Khilwani et al., 2008):  $Ab' = Ab + \alpha \delta_k$ , where  $\delta_k$  is a Cauchy random variable with the scale parameter  $t = 1$  and satisfies the density function  $f_{Cauchy}(x) = \frac{t}{\pi(t^2 + x^2)}$ .
- Static Hypermutation  $L_{h1}$  (Cutello et al., 2004; Gong et al., 2008): the number of mutations is independent from the affinity of the antibody. That is to say,  $Ab'$  will undergo a constant number  $c$  of mutation times. Each mutation act on  $Ab$  is implemented through replacing a certain number of  $Ab$  at a random dimension with a random integer between 0 and 9 (Gong et al., 2008).
- Proportional Hypermutation  $L_{h2}$  (Cutello et al., 2004): the number of mutations is proportional to the normalized affinity value, that is,  $\hat{f}(Ab) \times c \times D$ , where  $\hat{f}(Ab)$  is the normalized affinity distributed in the interval of  $[0, 1]$ .  $c$  is a constant number, representing the maximum mutation intensity.
- Inversely proportional hypermutation  $L_{h3}$  (Cutello et al., 2004, 2005, 2006): the number of mutations is inversely proportional to the normalized affinity value, i.e., the higher affinity of an antibody, the less times of mutations will be carried out on it. It is reasonable to make such an inverse choice, since better antibodies usually contain more useful information for evolution. Too many mutations might have higher probability to destroy these information, thus depressing the learning performance.
- Hypermacromutation  $L_m$  (Cutello et al., 2004): the number of mutations is independent from the affinity and the parameter  $c$ . Instead, the operator mutates at most  $j - i + 1$  values in the interval of  $[i, j]$ , where two randomly generated integers  $i$  and  $j$  satisfy the condition of  $i < j \leq D$ .
- Lateral interaction mutation  $L_{li}$  (Cutello et al., 2006; Pavone et al., 2011): in addition to hypermutation and receptor editing, the lateral interaction during different antibodies also takes place according to the idiotypic network theory (Gao et al., 2008). In other words, each paratope on an antibody can not only recognize a foreign antigen, but also can be recognized by external idiotopes. Motivated by this mechanism, similar to the crossover operator in evolutionary computation, an antibody is attracted by other antibodies, i.e.,  $Ab'_i = (1 - \beta) \times Ab_i + \beta Ab_j$ , where  $Ab_j \neq Ab_i$  is a randomly selected antibody in the population.
- Baldwinian learning  $L_{bl}$  (Gong et al., 2010): learning mechanism can provide an easy evolutionary path towards co-adapted alleles in environments, by means of employing differential information during other antibodies. It is realized as  $Ab'_i = Ab_i + s \times (Ab_j - Ab_k)$  in a probability of  $p$ , where  $i \neq j \neq k$ ,  $Ab_j$  and  $Ab_k$  are randomly selected from the population, and  $s$  represents the Baldwinian learning strength.

Intuitively, all the above eight learning operators are able to evolve antibodies to matured ones in semi-blind manners, although some of the matured ones might possess lower affinities. However, as the parallel feature of the immune algorithm, there did exist a probability of making progress to improve the affinity of antibodies. After the clonal selection progress, the most improved antibodies are reserved and enter into the next generation of evolution.

### Search direction based learning operator

Even though the above learning operators used in IA can explore/exploit the solution space in an effective manner, as we observed, they are not fully developed from the aspect of utilizing the information in environment. In Fig. 1, we summarized the characteristics of the learning operators. The solid rectangle  $S$  show the solution space of the optimization problem. The dashed circles denote contour lines of affinity, and the inner circles indicate that they represent higher affinities than the outer ones.

From Fig. 1, we can notice that the learning mechanisms used in (1)-(6) on the antibody  $Ab$  only utilize random perturbation on the antibody itself, while those in (7)-(8) make use of information in the environment. As reported in (Cutello et al., 2006; Gong et al., 2010), learning from the environment provides an encouraging alternative method, probably a more easy way to achieve better search performance. In details, the mechanism in (7) uses the information of a randomly selected antibodies in the population to

guide the current search. A successful guide is strongly depending on the quality of the selected guiding antibody  $Ab_j$ , implying that there must be amount of redundant search if the guiding antibody is far away from the global optimal solution. Instead, the mechanism in (8) utilizes the differential information between two other antibodies  $Ab_j$  and  $Ab_k$  in the population. The learning acting on this differential information might have ability to use the mutual beneficial components, thus exhibiting more promising properties for searching.

Based on the above analysis, we can find that the mechanisms used in (7) and (8) don't use any measurable knowledge from the population, i.e., the guiding antibodies ( $Ab_j$  and  $Ab_k$ ) are randomly selected without any relevance of the current antibody  $Ab$ , therefore hindering the effectiveness of the learning performance. In view of the limitations of the above learning operators, we propose a new search direction based learning operator  $L_{sd}$ , not only to provide another alternative mutation method, but also aiming to achieve a better search capacity. The  $L_{sd}$  is formulated in Eqs. (1)-(3):

In these equations,  $\Delta_{repulsion}$  and  $\Delta_{attraction}$  are repulsion and attraction effect on  $Ab_i$  respectively. In a single learning procedure of  $L_{sd}$ , if a randomly selected guiding antibody  $Ab_j$  whose affinity is lower than the base antibody  $Ab_i$ , then the repulsion effect will be implemented with a probability of  $p_r$ , for the purpose of preventing the base antibody from entering undesired region of the search space. On the other hand, the attraction effect takes place with a probability of  $p_a$  when the affinity of the selected guiding antibody  $Ab_k$  is higher, thus enhancing the capacity of exploiting the promising regions of the search space. In addition, to improve the randomness of the learning mechanism, the attraction and repulsion scaling factors  $\alpha_1$  and  $\alpha_2$  are set as random numbers generated in the interval  $[0, 1]$ . From Eq. (3), it is clear that the search direction of the base antibody is guided to move towards the regions with higher affinity, and meanwhile away from the regions with lower affinity, thus enabling the algorithm to possess better exploitation capacity and the ability of jumping out of local optimum.

## Experimental results and discussions

The computational progresses of nine learning operators used in IA described above have been implemented in C++ program under Visual Studio 2010. In order to evaluate the performance of the proposed  $L_{sd}$  learning operator, it is validated using some well-known benchmark numerical optimization problems obtained from the literatures (Yao et al., 1999; Cutello et al., 2006; Gong et al., 2010). Table 1 lists the details of the benchmark functions.  $f_1 - f_5$  are unimodal functions which are relatively easy to be optimized, but the difficulty increases as the dimension size increases.  $f_6$  is the step function, while  $f_7$  is a noisy quartic function.  $f_8 - f_{13}$  are multimodal functions with plenty of local minima which represent the most difficult class of problems for many op-

timization algorithms;  $f_{14} - f_{23}$  is a multimodal function with only a few local optima. The different type of benchmark functions test the searching ability of learning operators from different aspects, that is, unimodal functions tend to reflect the convergence speed of the operator in a direct manner, while multimodal functions are likely to estimate the operator's capacity of escaping from local optima.

Owing to the random nature of the IA and the learning operators, to evaluate the performance of each learning operator, their performance cannot be judged by the result of a single run. Many trials with independent population initialization should be made to obtain a useful conclusion of the performance of the approach. Therefore, in this study the results are obtained in 30 trials. In the experiment, the user-defined parameters are set as follows: the population size is set to be 30, the clone size is 5. It is worth mentioning that we use equal cloning strategy in this study to reduce the influences of cloning operator. By doing so, each antibody in the population has the same probability to undergo the learning mechanism, thus we can make a direct comparison of the performance during all learning operators. In addition, the termination condition of the algorithm is set to be that when the maximum number of function evaluations reaches 150000. Fig. 2 depicts the sketch of the Sphere function  $f_1$  when its dimension  $D$  is set to be 2, and the corresponding convergence graphs of each learning operator. It is obvious that, for such unimodal function, all learning operators can evolve the antibodies effectively. In particular, the learning operator  $L_{sd}$  possesses the fast learning speed and the most precise solution.

To further demonstrate the effectiveness and robustness of the proposed  $L_{sd}$ , all learning operators are carried out on all tested 23 benchmark functions. One of the effective strategies to perform a comparative study between the variants of IAs is to use the oracle-based view of computation (Wolpert and Macready, 1997). Based on this method, the best solution should be found within a certain number of function evaluations. Herein, the best values can be used for comparison because of the equal number of function evaluation for all operators in all cases. To make an intuitive comparison during the variants, the results of best run are normalized between 0 and 1, therefore the worst and best values of each best solution are changed to 0 and 1, respectively. The normalized results for all benchmark functions are presented in Table 2. To achieve a general conclusion based on the oracle-based view, three kinds of the sum of scores and rank of each learning operator are presented in this table. The symbol  $\sum_u$  denotes the sum of scores on unimodal function  $f_1 - f_5$ , while  $\sum_m$  is the sum on multimodal functions  $f_8 - f_{13}$ .  $\sum$  represents the total sum on all tested benchmark functions. At first glance, it is clear that the learning operator  $L_{sd}$  works very well because it has the best performance with the score of 22.940 to 23, and has a rank of 1 among 9 operators. Furthermore, as the  $\sum_u$  of

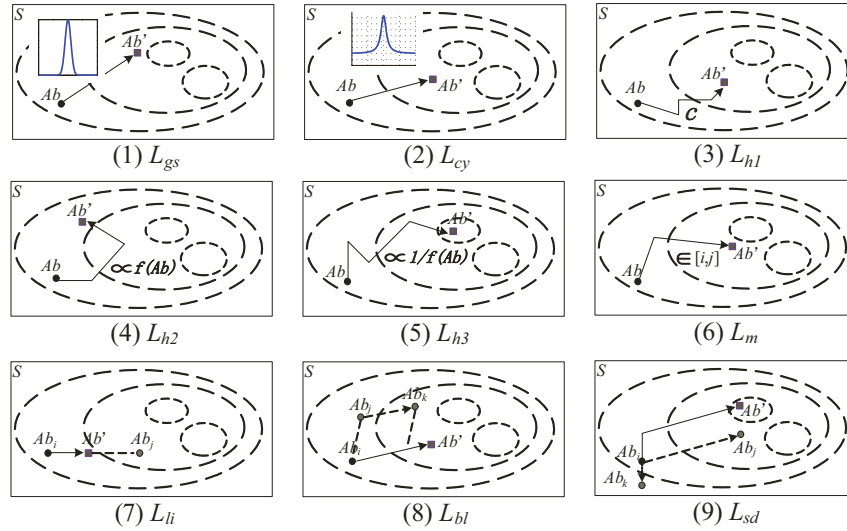

Figure 1: The learning characteristics of all nine operators.

$L_{sd}$  is 4.941 which is also the best one among all operators, thus confirming that  $L_{sd}$  has a fastest convergence speed for unimodal functions. On the other hand, the biggest value of  $\sum_m$  of  $L_{sd}$  also verifies the capability of escaping from local optimum for multimodal functions.

Based on Table 2, there are some remarks should be emphasized concerning all learning operators. The first six learning operators mutate the base antibody only utilizing random perturbation, while the last three ones make use of information in the population either semi-blind or search direction based. The population information utilization based learning operators have ranks of 1, 2, 3, significant better than the others, suggesting that the interaction of information in the population is likely to improve the search performance. Thus, we can conclude that the former operators mainly act as the exploitation in the search space, while the latter ones mainly employed as exploration. In the further, it is a promising research direction to combine one of former six operators with the one of latter ones, and it can be expected to achieve a better performance.

## Conclusions

In this paper, we made a comprehensive study on the learning operators used in the immunological algorithms. Nine different learning operators, maturing the antibody either by utilizing random perturbation or by utilizing the guiding information from other antibodies, are implemented and analyzed. In view of the limitations of the existing operators, the newly proposed search direction based learning mechanism can not only attract the antibody to promising regions in search space, but also preventing from entering undesired regions by means of the information contained in the antibodies with worse affinities. Experimental results on a large number of benchmark numerical optimization problems verified the effectiveness and robustness of  $L_{sd}$ , suggesting that the useful information during the whole population should be sufficiently utilized to improve the search performance of the algorithm.

## Abstract

The negative database (*NDB*) is the negative representation of original data. Existing work has demonstrated that *NDB* can be used to preserve privacy and hide information. However, most work about *NDB* is based on binary representation. In some applications which are naturally described in real-valued space, the binary negative database is hard to be applied appropriately. Therefore, the real-valued negative database is proposed in this paper, and reversing the real-valued negative database is proved to be an *NP*-hard problem. Moreover, an effective algorithm for generating real-valued negative databases is given. Finally, an example of applying the real-valued negative database to the privacy-preserving data publication is described, and it shows that the real-valued negative database is valuable in practice.

## Introduction

Nowadays, databases have become basic tools for storing data. As the privacy of data is widely concerned, the techniques which can preserve privacy while keeping the database services available are urgently needed. Traditional databases store the data with the form what it actually is. This way is called the positive representation of data, and the databases are called positive databases. The privacy of traditional databases is easy to be revealed when the databases are leaked. Although some cryptography methods can be applied to the positive databases, it is time-consuming to encrypt every entry in the databases and the encrypted databases cannot support basic database operations efficiently. Another way is to control the access of the positive database, but this way cannot eliminate all the security risks as there may be some internal attacks.

The negative database, which is inspired by Natural Immune System, was proposed by Esponda and his colleagues (Esponda et al., 2004a; Esponda et al., 2004b; Esponda et al., 2005; Esponda et al., 2007a; Esponda et al., 2009). In contrast to traditional databases, the negative database only stores the information in the complementary set of the original data. This way is called the negative representation of data. It has been proved that reversing the negative database with the binary representation (i.e. recovering the corresponding binary

positive database) is *NP*-hard (Esponda et al., 2004b; Esponda et al., 2009). Therefore, the binary negative database could be employed to protect data privacy. Some algorithms for generating binary negative databases from binary positive databases have been proposed, such as the prefix algorithm (Esponda et al., 2004b; Esponda et al., 2009), the *RNDB* algorithm (Esponda et al., 2004b; Esponda et al., 2009), the *q*-hidden algorithm (Jia et al., 2005; Esponda et al., 2007a) and the hybrid-*NDB* algorithm (Liu et al., 2011). Furthermore, some basic operations upon the negative database have been proposed, such as the negative Cartesian product, negative join and negative intersection (Esponda et al., 2004a; Esponda et al., 2005; Esponda et al., 2007b).

So far, most work about the negative database is based on the binary representation. However, in some applications which are naturally described in real-valued space, the negative database with the binary representation is not appropriate. Therefore, the real-valued negative database is proposed in this paper.

The negative database has already been introduced to some applications such as privacy preserving (Esponda et al., 2004b; Esponda et al., 2007a; Esponda et al., 2009), sensitive data collection (Esponda, 2006; Horey et al., 2007) and authentication (Dasgupta and Azeem, 2007; Dasgupta and Azeem, 2008). In this paper, an example of applying the real-valued negative database to the privacy-preserving data publication is given. This example demonstrates that the real-valued negative database is appropriate for the privacy-preserving data publication.

## Existing Work about Negative Databases

The negative database (*NDB*) was proposed by Esponda and his colleagues (Esponda et al., 2004a; Esponda et al., 2004b). Presently, most negative databases are based on the binary representation. The details of the binary negative database are described as follows (Esponda et al., 2004b; Esponda et al., 2009).

Assume the original data is a database which consists of  $n$  entries, i.e.  $DB = \{x_1, x_2, \dots, x_n\}$ , and each entry in  $DB$  is a binary string with length  $m$ . The universal set is  $U = \{0, 1\}^m$ .

\* Corresponding author. Tel: 86-551-63602824

The complementary set of  $DB$  is denoted as  $U-DB$ , and the negative database  $NDB$  only stores the elements that belong to  $U-DB$ . As there are usually too many binary strings belong to  $NDB$ , a “don’t care” symbol ‘\*’ is introduced to compress  $NDB$  to a reasonable size. Each entry in  $NDB$  is a string defined upon the alphabet  $\{0, 1, *\}$  with length  $m$ . The positions with value 0 or 1 are called specified positions, and those with symbol ‘\*’ are called unspecified positions. The symbol ‘\*’ represents 0 or 1 at a given position. If all the entries in  $U-DB$  are covered by  $NDB$ ,  $NDB$  is said to be complete. Any binary string  $s$  is said to be matched with (or covered by) an entry  $y$  in  $NDB$  if and only if the value at each position of  $s$  is identical to that of  $y$  or the corresponding value of  $y$  is ‘\*’. With the unspecified value ‘\*’, multiple different negative databases can be generated from the same positive database.

It has been proved that reversing the binary negative database (i.e. recovering the corresponding binary positive database) is an  $NP$ -hard problem (Esponda et al., 2004b; Esponda et al., 2009). If reversing a negative database is computationally infeasible, the negative database is said to be hard-to-reverse, otherwise it is said to be easy-to-reverse.

Some algorithms for generating the binary negative database from a binary positive database have been proposed. The prefix algorithm (Esponda et al., 2004b; Esponda et al., 2009) is the first algorithm for generating binary negative databases, and it is compact and efficient. The binary negative database generated by the prefix algorithm is complete but easy-to-reverse. In order to overcome this shortcoming, the  $RNDB$  algorithm (Esponda et al., 2004b; Esponda et al., 2009) was proposed. The  $RNDB$  algorithm embeds some random factors for generating binary negative databases which are possibly hard-to-reverse. However, the hard-to-reverse property of the binary negative databases generated by the  $RNDB$  algorithm could not be guaranteed, and the size of those binary negative databases could be too large. The  $q$ -hidden algorithm (Jia et al., 2005; Esponda et al., 2007a) was proposed for the binary positive databases that contain only one entry, and it is very efficient. The generated binary negative databases are not complete, but hard-to-reverse on average. The hybrid- $NDB$  algorithm (Liu et al., 2011) combines the prefix algorithm with the  $q$ -hidden algorithm to generate binary negative databases that are both complete and hard-to-reverse on average. It is noted that the “hard-to-reverse” property mentioned here means that the SAT solvers with local search strategy (e.g. WalkSAT (Selman et al., 1995)) could not reverse the negative databases on average.

In real-world applications, real-valued databases are often used. However, it is not convenient to employ the binary negative database to represent a real-valued database. Therefore, the real-valued negative database is studied in this paper. It is noted that earlier work about the negative database is the negative selection algorithm (Forrest et al., 1994; Ji and Dasgupta, 2007). The binary negative database is closely related to the negative selection algorithm with the binary representation (Forrest et al., 1994; Ji and Dasgupta, 2007), while their objectives and generation algorithms are obviously different. Hence, the real-valued negative database is also related to (but different from) the negative selection algorithm with the real-valued representation (González et al., 2003; Ji

and Dasgupta, 2004; Ji and Dasgupta, 2006; Ji and Dasgupta, 2007).

## The Real-Valued Negative Database

Assume real-valued positive database ( $DB$ ) contains  $n$  entries, i.e.  $DB = \{x_1, x_2, \dots, x_n\}$ . There are  $m$  attributes  $\{R_1, R_2, \dots, R_m\}$  in  $DB$ , and the domain of each attribute  $R_k$  ( $k = 1 \dots m$ ) is  $I_k = [l_k, u_k]$ .  $l_k$  is the lower bound and  $u_k$  is the upper bound. The bounds  $l_k$  and  $u_k$  are both real values, i.e.  $l_k \in R$ ,  $u_k \in R$ . Each entry  $x_i$  ( $i = 1 \dots n$ ) is a vector of  $m$  real values, and each value  $x_i[k]$  ( $k = 1 \dots m$ ) belongs to the domain of  $k^{th}$  attribute, i.e.  $x_i[k] \in I_k$ .

The real-valued negative database only stores the information that belongs to the complementary set of the real-valued positive database. Since the instances covered by the real-valued negative database are usually too many to be presented exactly, intervals are introduced to compress them.

Suppose  $a$  is an entry with  $m$  real values, and  $v$  is an entry with  $m$  intervals. Entry  $a$  is matched with (or covered by) entry  $v$  if and only if following condition is satisfied.

$$a[k] \in v[k], \quad k = 1, 2, \dots, m \quad (1)$$

Based on above matching rule, the real-valued negative database for  $DB$  can be defined as follows.

**Definition 1.** (*Real-Valued Negative Database*) Giving the real-valued positive database  $DB$  and the universal set  $U = I_1 \times I_2 \times \dots \times I_m$ , the real-valued negative database ( $RvNDB$ ) for  $DB$  is a compressed representation of  $U-DB$ . Each entry in  $RvNDB$  consists of  $m$  intervals, and does not cover any entries in  $DB$ .

If  $RvNDB$  covers the whole complementary set of  $DB$ ,  $RvNDB$  is said to be complete. Otherwise,  $RvNDB$  is said to be incomplete. A simple database query can be processed directly upon the real-valued negative database. For any  $s$  (a vector with  $m$  real values), if it is covered by  $RvNDB$ , it does not belong to  $DB$ ; if  $s$  is not covered by  $RvNDB$  and  $RvNDB$  is complete, it belongs to  $DB$ .

As any two entries in the real-valued negative database may intersect with each other, one real-valued positive database can be mapped to multiple real-valued negative databases. An example is given in table 1.

**Table 1.** An example of  $RvNDB$ s

| $DB$     | $NDB_1$               | $NDB_2$                 |
|----------|-----------------------|-------------------------|
| 0.2, 0.8 | [0, 0.2), [0, 1.0]    | [0, 0.2), [0.8, 1.0]    |
|          | [0.21, 1.0], [0, 1.0] | [0.21, 1.0], [0.8, 1.0] |
|          | [0, 1.0], [0, 0.8]    | [0, 1.0], [0, 0.8]      |
|          | [0, 1.0], [0.81, 1.0] | [0, 1.0], [0.81, 1.0]   |

Notes: There are two attributes in  $DB$ . The domains of the two attributes are both  $[0, 1.0]$ .

## The $NP$ -Hard Property of $RvNDB$ s

In this section, reversing the real-valued negative database ( $RvNDB$ ) is proved to be an  $NP$ -hard problem. The proofs are

similar to the work in (Esponda et al., 2004b; Esponda et al., 2009). Based on the hardness of reversing the real-valued negative database, the real-valued negative database can be used to preserve privacy.

**Problem 1.** Is the positive database of  $RvNDB$  non-empty? That is, is there any entry that is not covered by  $RvNDB$ ?

**Problem 2.** Can  $RvNDB$  be reversed to obtain the entries in the corresponding positive database? That is, can any entry that is not covered by  $RvNDB$  be found?

**Lemma 1.** Problem 1 is *NP*.

*Proof.* Giving any entry  $w$  which consists of  $m$  real values, if an algorithm can check whether it is the solution in polynomial time, problem 1 is *NP*. Obviously, the complexity of checking whether the entry  $w$  is matched with (or covered by) an entry  $y_i$  in  $RvNDB$  is  $O(m)$  ( $m$  is the number of attributes). Then the complexity of checking whether  $RvNDB$  covers the entry  $w$  is  $O(m \cdot |RvNDB|)$  ( $|RvNDB|$  is the number of entries in  $RvNDB$ ). Therefore, checking whether an entry  $w$  is the solution of problem 1 can be done in  $O(m \cdot |RvNDB|)$ , and problem 1 is *NP*.

**Lemma 2.** Any CNF-SAT instance  $\phi$  can be converted to a real-valued negative database  $RvNDB_\phi$ .

*Proof.* Giving any CNF-SAT instance  $\phi$  with  $n$  clauses and  $m$  variables  $x_1, x_2, \dots, x_m$ ,  $\phi = C_1 \wedge C_2 \wedge \dots \wedge C_n$ , a real-valued negative database  $RvNDB_\phi = \{y_1, y_2, \dots, y_n\}$  with  $m$  attributes and  $n$  entries can be constructed as follows.

- (1) Divide the domain of each attribute into two segments:  $[l_k, p_k)$  and  $[p_k, u_k]$  ( $k = 1, 2, \dots, m$ ). Then encode three intervals as follows.

$$\begin{cases} [l_k, p_k) = 0 \\ [p_k, u_k] = 1 \\ I_k = * \end{cases} \quad (2)$$

As the interval  $I_k$  covers both interval  $[l_k, p_k)$  and  $[p_k, u_k]$ , the symbol '\*' represents either 0 or 1.

- (2) Each clause  $C_i$  is mapped to an entry  $y_i$  of  $RvNDB_\phi$ , and a binary negative database denoted as  $eNDB_\phi = \{e_1, e_2, \dots, e_n\}$  is constructed according to  $RvNDB_\phi$ .
  - (a) If the  $k^{\text{th}}$  variable is presented as  $x_k$  in  $C_i$ ,  $[l_k, p_k)$  is assigned to  $y_i[k]$ , and  $e_i[k]$  is set as 0.
  - (b) If the  $k^{\text{th}}$  variable is presented as  $\bar{x}_k$  in  $C_i$ ,  $[p_k, u_k]$  is assigned to  $y_i[k]$ , and  $e_i[k]$  is set as 1.
  - (c) If the  $k^{\text{th}}$  variable does not appear in  $C_i$ ,  $I_k$  is assigned to  $y_i[k]$ , and  $e_i[k]$  is set as '\*'.

After all the clauses of the CNF-SAT instance are mapped to entries, the real-valued negative database  $RvNDB_\phi$  denoted with intervals is constructed. The database  $eNDB_\phi$  is the binary form of  $RvNDB_\phi$  and they can be converted to each other easily. The  $eNDB_\phi$  has the same structure with the binary negative database defined in (Esponda et al., 2004b; Esponda et al., 2009).

**Lemma 3.** Any entry in  $eNDB_\phi$  is not the true assignment of  $\phi$ .

*Proof.* Obviously, if assign  $e_i[k]$  ( $k = 1 \dots m$ ) to the  $k^{\text{th}}$  variable  $x_k$ , the entry  $e_i$  is not a true assignment of  $C_i$ . Because each entry in  $eNDB_\phi$  cannot satisfy at least one clause of  $\phi$ , it is not the true assignments of  $\phi$ .

**Lemma 4.** Each true assignment of the CNF-SAT instance  $\phi$  corresponds to a real-valued entry not covered by  $RvNDB_\phi$  and vice versa.

*Proof.* For any true assignment  $a$  of the CNF-SAT instance  $\phi$ , as every clause of  $\phi$  is satisfied by  $a$  and every entry in  $eNDB_\phi$  is not the true assignment of  $\phi$ , at least one bit of  $a$  is different from each entry in  $eNDB_\phi$ . That is to say,  $a$  is not covered by  $eNDB_\phi$ . According to equation 2, the assignment  $a$  can be converted to an entry  $v$  that consists of intervals, and obviously the entry  $v$  is not covered by  $RvNDB_\phi$ .

For any entry  $w$  consists of  $m$  real values and not covered by any entries in  $RvNDB_\phi$ , it could be encoded to a binary string  $a$  as follows.

$$a[k] = \begin{cases} 0 & w[k] \in [l_k, p_k) \\ 1 & w[k] \in [p_k, u_k] \end{cases}, \quad k = 1, 2, \dots, m \quad (3)$$

As  $w$  is not covered by any entry  $y_i$  ( $i = 1, \dots, n$ ) in  $RvNDB_\phi$ , there is at least one attribute  $k$  that  $w[k]$  is not covered by  $y_i[k]$ , and the encoding result  $a[k]$  is different from  $e_i[k]$  as well, i.e.  $a[k] = \bar{e}_i[k]$ . According to the encoding of  $RvNDB_\phi$ , if assign  $a[k]$  to  $x_k$ , the clause  $C_i$  will be satisfied. Moreover, since  $w$  is not covered by all the entries in  $RvNDB_\phi$ , all the clauses in  $\phi$  are satisfied by  $a$ , and  $a$  is a true assignment of the CNF-SAT instance  $\phi$ .

**Theorem 1.** Problem 1 is *NP*-complete.

*Proof.* According to lemma 4, the problem of checking the satisfiability of the instance  $\phi$  is equivalent to the problem 1 for  $RvNDB_\phi$ . Furthermore, due to the instance  $\phi$  is chosen arbitrarily, any instance of the CNF-SAT can be converted to a special real-valued negative database. Therefore, problem 1 is *NP*-complete.

**Theorem 2.** Problem 2 is *NP*-hard.

*Proof.* Based on lemma 1, 2, 3, 4 and theorem 1, this theorem is immediately proved.

## Generation Algorithm for $RvNDB$ s

Some generation algorithms for the binary negative database have been proposed (Esponda et al., 2004b; Jia et al., 2005; Esponda et al., 2007a; Esponda et al., 2009; Liu et al., 2011). Based on these generation algorithms, an algorithm for generating real-valued negative databases is proposed in this section.

Giving a positive database  $DB = \{x_1, x_2, \dots, x_n\}$ , and there are  $m$  attributes in  $DB$ . Each entry in  $DB$  is a vector of  $m$  real values. The procedure of the generation algorithm for the real-valued negative database from  $DB$  is described as follows.

- (1) Preprocessing: Divide the domains of attributes in  $DB$ , and convert  $DB$  to a real-valued database  $DB^I$  which consists of intervals.
- (2) Encoding: Encode  $DB^I$  to a binary positive database  $DB^2$ .
- (3) Generating: Input  $DB^2$  to an algorithm for generating a binary negative database from the binary positive database such as the  $q$ -hidden algorithm or the prefix algorithm, and output a binary negative database  $NDB^2$ .
- (4) Decoding: Decode  $NDB^2$  to a real-valued negative database  $RvNDB$  which consists of intervals.

### Phase 1: Preprocessing

The preprocessing phase contains two processes: the dividing process and the converting process. In the dividing process, the domain of each attribute in  $DB$  is divided into several distinct intervals. In the converting process, the values of each entry in  $DB$  are converted to the intervals which they belong to.

**Dividing Process.** The domain of each attribute in  $DB$  is divided to a set of intervals. For any  $k$  ( $k = 1 \dots m$ ), the interval set  $P_k = \{p_{k,1}, p_{k,2}, \dots, p_{k,num_k}\}$ , where  $num_k$  is the number of intervals in  $P_k$ .

The set  $P_k$  should be generated according to the requirements for real-life applications and satisfy following basic conditions.

- (1) The union of all the intervals in  $P_k$  equals to  $I_k$ , i.e.

$$p_{k,1} \cup p_{k,2} \cup \dots \cup p_{k,num_k} = I_k \quad (4)$$

- (2) The intersection between any two different intervals in  $P_k$  is the empty set, i.e.

$$p_{k,i} \cap p_{k,j} = \emptyset, \quad \forall 1 \leq i < j \leq num_k \quad (5)$$

- (3) Since  $DB$  will be encoded to a binary database, ideally, the number of intervals in  $P_k$  should be the exponent of 2.

|                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          |
|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <b>Divide algorithm</b><br>Input: $I = \{I_1, I_2, \dots, I_m\}$ , $Num = \{num_1, num_2, \dots, num_m\}$<br>Output: $P = \{P_1, P_2, \dots, P_m\}$                                                                                                                                                                                                                                                                                                                                                                                                      |
| <ol style="list-style-type: none"> <li>1. <b>For</b> the <math>k^{th}</math> (<math>k = 1 \dots m</math>) attribute <b>do</b></li> <li>2.   <math>low \leftarrow l_k</math>, <math>unit \leftarrow (u_k - l_k)/num_k</math></li> <li>3.   <b>For</b> <math>i = 1</math> to <math>num_k - 1</math> <b>do</b></li> <li>4.     <math>up \leftarrow low + unit</math></li> <li>5.     Add <math>[low, up)</math> to <math>P_k</math></li> <li>6.     <math>low \leftarrow up</math></li> <li>7.   Add <math>[low, u_k]</math> to <math>P_k</math></li> </ol> |

**Figure 1.** An algorithm for dividing process

Although the dividing process depends on the requirements of real-life applications, a simple algorithm is given in figure 1. The algorithm in figure 1 equally divides each domain  $I_k$  ( $k = 1 \dots m$ ) into  $num_k$  intervals. This algorithm can be applied to

some applications such as the privacy-preserving data publication.

**Converting Process.** According to above dividing process,  $DB$  can be converted to a real-valued positive database  $DB^I$  which consists of intervals as follows.

Let  $DB^I = \{t_1, t_2, \dots, t_n\}$ . For each entry  $x_i$  ( $i = 1 \dots n$ ) in  $DB$ , the value of the  $k^{th}$  ( $k = 1 \dots m$ ) attribute is converted to the interval which  $x_i[k]$  belongs to in  $P_k$ , i.e.

$$t_i[k] = p_{k,j} \quad \text{iff} \quad x_i[k] \in p_{k,j} \quad (6)$$

### Phase 2: Encoding

In order to generate real-valued negative databases, the real-valued positive database  $DB^I$  is encoded to a binary database, and then an algorithm for generating negative databases from binary positive databases can be employed.

For the  $k^{th}$  ( $k = 1 \dots m$ ) attribute, since any two different intervals are not intersected with each other and the number of the intervals in  $P_k$  is the exponent of 2, it is easy to encode  $num_k$  intervals in  $P_k$  as  $num_k$  binary strings with length  $\log_2(num_k)$ . According to the encoding of intervals in  $P_k$ , the entries in  $DB^I$  can be converted to binary strings. The details of the encoding phase are shown in figure 2.

The algorithm shown in Figure 3 is used for generating the binary code from an integer. If the length of the binary code is less than  $l$ , some zeros will be attached after it. It follows that all the generated binary strings have the same length. In the encoding phase, this algorithm is employed to encode the intervals in  $P_k$  ( $k = 1 \dots m$ ) according to their indexes.

#### Encode algorithm

Input:  $DB^I = \{t_1, t_2, \dots, t_n\}$ ,  $P = \{P_1, P_2, \dots, P_m\}$   
 Output:  $DB^2 = \{s_1, s_2, \dots, s_n\}$

1. **For** each entry  $t_i$  ( $i = 1 \dots n$ ) in  $DB^I$  **do**
2.   **For** the  $k^{th}$  ( $k = 1 \dots m$ ) attribute **do**
3.      $l \leftarrow \log_2(num_k)$
4.     **If**  $t_i[k]$  is the  $j^{th}$  interval in  $P_k$  **then**
5.        $s_i[k] \leftarrow \text{binaryCode}(j-1, l)$

**Figure 2.** The algorithm for encoding phase

#### binaryCode(v, l)

Input: an integer  $v$  and length  $l$   
 Output: a binary string  $str$  with length  $l$

1.  $i \leftarrow 1$
2. **While**  $i \leq l$  **do**
3.    $str[i] \leftarrow v \bmod 2$
4.    $v \leftarrow v/2$
5.    $i \leftarrow i + 1$

**Figure 3.** Generating the binary code from an integer

### Phase 3: Generating

In the encoding phase, a binary database  $DB^2$  has been generated from the real-valued positive database  $DB^1$ . In the generating phase,  $DB^2$  is inputted to an algorithm for generating negative databases from the binary positive database, such as the prefix algorithm (Esponda et al., 2004b; Esponda et al., 2009), the *RNDB* algorithm (Esponda et al., 2004b; Esponda et al., 2009) and the *q*-hidden algorithm (Jia et al., 2005; Esponda et al., 2007a), and the generation algorithm outputs a binary negative database  $NDB^2 = \{z_1, z_2, \dots, z_N\}$ .

### Phase 4: Decoding

In the generating phase, a binary negative database  $NDB^2$  is obtained from the binary positive database  $DB^2$ . It is not convenient to use the binary negative database in the real-valued space. Therefore, in the decoding phase, the binary negative database  $NDB^2$  is converted to a real-valued negative database *RvNDB*.

|                                                                            |  |
|----------------------------------------------------------------------------|--|
| <b>Decode algorithm</b>                                                    |  |
| Input: $NDB^2 = \{z_1, z_2, \dots, z_N\}$ , $P = \{P_1, P_2, \dots, P_m\}$ |  |
| Output: <i>RvNDB</i>                                                       |  |
| 1. <b>For</b> each entry $z_i$ ( $i = 1 \dots N$ ) in $NDB^2$ <b>do</b>    |  |
| 2. <b>For</b> the $k^{\text{th}}$ ( $k = 1 \dots m$ ) attribute <b>do</b>  |  |
| 3. $Q_k \leftarrow \text{Extend\_Pattern}(z_i[k], P_k)$                    |  |
| 4. $RvNDB \leftarrow RvNDB \cup (Q_1 \times \dots \times Q_m)^{**}$        |  |

**Figure 4.** The algorithm for decoding phase

|                                                                                                                     |  |
|---------------------------------------------------------------------------------------------------------------------|--|
| <b>Extend_Pattern(<i>str</i>, <math>P_k</math>)</b>                                                                 |  |
| Input: A string <i>str</i> defined upon alphabet $\{0, 1, *\}$ , and $P_k$                                          |  |
| Output: A set <i>W</i> of intervals which is decoded from <i>str</i>                                                |  |
| 1. Initialize <i>W</i> as the empty set                                                                             |  |
| 2. Set $B_p$ as the unspecified positions of <i>str</i>                                                             |  |
| 3. <b>For</b> every possible assignment <i>T</i> of $B_p$ <b>do</b>                                                 |  |
| 4.     Let <i>str'</i> be the same with <i>str</i> but the unspecified positions are assigned according to <i>T</i> |  |
| 5.     Let <i>temp</i> be the decimal value of <i>str'</i>                                                          |  |
| 6.     Add $p_{k, \text{temp}+1}$ to <i>W</i>                                                                       |  |
| 7. Merge the adjacent intervals in <i>W</i>                                                                         |  |

**Figure 5.** Decoding a string defined upon alphabet  $\{0, 1, *\}$  to a set of intervals

The algorithm for the decoding phase is given in figure 4. Since the entries in  $NDB^2$  are defined upon the alphabet  $\{0, 1, *\}$ , and the symbol ‘\*’ represents either 0 or 1 at a given position, each entry may cover multiple strings of specified

\*\* It is noted that the cross product operation  $(Q_1 \times \dots \times Q_m)$  could be compressed to a new type of entry  $y_Q = (Q_1, Q_2, \dots, Q_m)$  for decreasing the size of *RvNDB*. Consequently, an entry in *RvNDB* could consist of *m* sets of intervals.

values (i.e. 0 and 1). An extra algorithm for decoding a string defined upon the alphabet  $\{0, 1, *\}$  to a set of intervals is given in figure 5.

The algorithm in figure 5 enumerates every specified string which is covered by the string *str*, and converts these specified strings to intervals. Finally, the adjacent intervals in *W* are merged.

## Application to the Privacy-Preserving Data Publication

As sensitive data has been involved in many applications nowadays, the privacy preserving of data has been widely concerned. The privacy-preserving data publication is a technique which can both preserve the privacy and maintain the utility of the published data.

The data generalization is an important technique for protecting sensitive data and preserving privacy (Fung et al., 2010). In the preprocessing phase of the generation algorithm for the real-valued negative database, the conversion from real values to intervals can be regarded as the generalization of real values, and the dividing of domains determines the generalized intervals. Therefore, when apply the real-valued negative database to the privacy-preserving data publication, the first phase can be replaced by some generalization techniques, such as some algorithms that can satisfy the *k*-anonymity principle (Sweeney, 2002). Then, a real-valued negative database can be generated from the generalized positive database through the generation algorithm described in the former section.

An example of applying the real-valued negative database to the privacy-preserving data publication is given as follows. The original data is shown in table 2. There are four attributes in the original positive database, and the attribute ‘Name’ is the explicit identifier. The combination of attributes <Age, Postcode> is regarded as the quasi-identifiers. The sensitive attribute is ‘Salary’. The domains of the last three attributes (i.e.  $I(\text{Age})$ ,  $I(\text{Postcode})$  and  $I(\text{Salary})$ ) are divided as follows.

$I(\text{Age}) = [0, 150]$

Divided as:  $\{[0, 20), [20, 40), [40, 70), [70, 150]\}$

Encoded as:  $\{00, 01, 10, 11\}$ .

$I(\text{Postcode}) = [00000, 50000]$

Divided as:  $\{[00000, 10000), [10000, 20000), [20000, 30000), [30000, 50000]\}$

Encoded as:  $\{00, 01, 10, 11\}$ .

$I(\text{Salary}) = [0, 100.0]$

Divided as:  $\{[0, 10.0), [10.0, 20.0), [20.0, 50.0), [50.0, 100.0]\}$

Encoded as:  $\{00, 01, 10, 11\}$ .

**Table 2.** The original database

| Name  | Age | Postcode | Salary (k\$) |
|-------|-----|----------|--------------|
| Alice | 16  | 21000    | 5.5          |
| Bob   | 10  | 25000    | 65.0         |
| John  | 55  | 16000    | 50.5         |
| Bill  | 62  | 11000    | 25.3         |
| David | 42  | 13000    | 15.5         |

The generalized data which satisfies 2-anonymity principle (the  $k$ -anonymity principle demands that each entry in the published database cannot be distinguished from at least other  $k-1$  entries (Sweeney, 2002)) is shown in table 3. The binary positive database is shown in table 4. The binary negative database generated by the prefix algorithm (Esponda et al., 2004b; Esponda et al., 2009) from the binary positive database is shown in table 5. Finally, the real-valued negative database decoded from the binary negative database is shown in table 6.

**Table 3.** The real-valued positive database which consists of intervals

| Age      | Postcode       | Salary (k\$)  |

## Discussion

The real-valued negative database can be applied to the privacy-preserving data publication. The preprocessing phase of the generation algorithm for the real-valued negative database could be replaced by an existing generalization algorithm. The privacy of the published data is preserved through not only the generalization but also the real-valued negative database. If high data precision is expected, the generalized intervals can be controlled to small ranges. Even if the sensitive data is not generalized, it is still under the protection of the negative representation. If the real-valued negative database is complete, it can be considered as “equivalent” to the generalized positive database and no extra information is lost. Furthermore, since the relationship between the real-valued positive database and the real-valued negative database is one-to-many, and it is hard to check whether two real-valued negative databases correspond to the same positive database (the hardness could be roughly controlled through the generation algorithm for negative databases). Therefore, the real-valued negative database could be properly applied to the privacy-preserving data republication (Xiao and Tao, 2007) and the privacy-preserving publication of dynamic data (Jian et al., 2007; Xiao and Tao, 2007; Bu et al., 2008).

## Conclusions and Future Work

Since the data in some applications is naturally represented in real-valued space, it is difficult to apply binary negative databases properly. Therefore, the real-valued negative database is proposed in this paper. Reversing the real-valued negative database is proved to be an  $NP$ -hard problem, and it follows that the real-valued negative database could be employed to protect data privacy. Based on the generation algorithms for the binary negative database, an effective algorithm for generating real-valued negative databases is proposed in this paper.

The real-valued negative database is applied to the privacy-preserving data publication in this paper. The privacy of the published data is under the protection of both the generalization and the negative representation. Furthermore, the balance between security and data precision could be controlled through the level of generalization and the generation algorithm for the real-valued negative database.

Although the definition and a generation algorithm for the real-valued negative database are given in this paper, some further work is expected. Since the generation algorithm for the real-valued negative database is based on the generation algorithms for the binary negative database, some more efficient generation algorithms which are dedicated to the real-valued negative database are expected to be proposed. Some operations for the real-valued negative database such as select, delete, insert, project, union, intersection, set difference, Cartesian product and join need to be designed urgently. These database operations are critical for extending the applications of the real-valued negative database. Moreover, some concrete and practical solutions of applying the real-valued negative database to the privacy-preserving data publication will be considered in future as well.

### Abstract

Cognisant of the gulf between engineers and immunologists that currently hinders a truly inter-disciplinary approach to the field of Artificial Immune Systems (AIS), we propose a redefinition of the term *AIS practitioner*, as an individual who identifies those components and interactions captured in computational immunology models that are responsible for a particular property of interest (POI), and distils from these a set of algorithms and principles that can be applied in an engineering domain. We outline the role of the cross-disciplinary practitioner and the potential benefits to the field.

### Introduction

The Artificial Immune Systems (AIS) field, which seeks to understand immune system operation and exploit these principles in engineering contexts, has been criticized for reasoning by metaphor (Stepney et al., 2005): algorithms are based on naïve biological analogies, are poorly understood, and weakly capture their inspiring biological properties. Various frameworks have been proposed that enable the richness of emergent biological properties to be translated into useful engineered systems. The conceptual framework (Stepney et al., 2005) proposed starting with a study of the immunological system, modeling it, and leading to the development of engineering algorithms. (Andrews, 2008) notes that the framework lacks guidance on selecting biological inspiration for particular engineering domains, and that evaluating a particular domains potential requires that it first be modeled. The immuno-engineering framework (Timmis et al., 2008), through better grounded in engineering by accounting for the physical properties of engineering systems (e.g. in terms of memory, processing power etc.), suffers the same problem.

The interdisciplinary approach to algorithmic development advocated by these frameworks is essential but raises practical issues: immunologists inform modeling efforts to realistically represent and aid biological understanding; engineers desire algorithms that can be theoretically analyzed, verified and validated to demonstrate desirable properties

and applicability to the problem at hand - the biological inspiration is irrelevant. Furthermore, engineers and immunologists will rarely interact; they have differing goals.

We propose redefining the term AIS practitioner, as an individual who identifies those components and interactions captured in computational immunology models that are responsible for a particular property of interest (POI), and to distil from these a set of algorithms and principles that can be applied in an engineering domain.

### The AIS Practitioner

The cross-disciplinary AIS practitioner possesses sufficient understanding to identify key modern-day engineering challenges, and appreciate how qualities exhibited by the immune system can help. They can comprehend computational immunology models, and derive therefrom the required algorithmic principles. Stripping away immunological nomenclature is vital; algorithmic components labeled T cells or lymph nodes are so abstract at this stage that they are meaningless and confusing.

We capture the AIS practitioners role as shown in figure 1. The box represents the space of abstract representations (models, simulations, algorithms, design principles) that capture a particular POI, a quality observed in the immune system and desired in an engineering solution, such as robustness, homeostasis, life-long learning, and adaptation, to name some examples (Hart and Timmis, 2008). Abstract representation complexity is represented vertically, whereas the domain of concern is depicted horizontally.

The bottom right corner represents the minimal rational representation (MRR), the minimal set of components/actors, interactions or principles responsible for manifestation of the POI, expressed free of immunological terminology. Its minimalism reflects the computational power and memory constraints of many engineering domains. The top right corner represents inefficient, sub-optimal and/or obfuscated abstract representations. Although they capture the POI, they contain superfluous interactions or components, and as such are not considered as suitable for adoption in engineering contexts. The top left contains detailed and com-

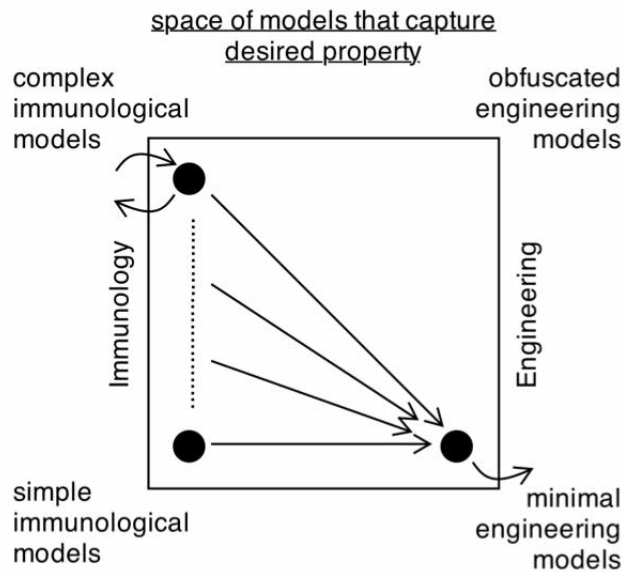

Figure 1: The space of abstract representation that capture a property of the immune system

plex models, representing, for example, large numbers of cells, pathways and spatial compartments. They may capture a great many immunological properties, in addition to the POI. The bottom left corner contains the minimal set of components and interactions responsible for the POI, and no other properties. Though minimal, these abstract representations exist in a form to benefit immunology, not in a form immediately applicable in engineering domains.

We consider the AIS practitioners role to derive the MRR, given some abstract representation occupying the left of the box. The components and interactions present that are redundant or unnecessary with respect to the POI are removed or abstracted. Depending on the nature of the POI, and the immune-inspired engineering solution being derived, the MRR may be expressed as an algorithm, or as design principles for constructing systems. The level of abstraction of the model is such that it should specify all necessary components of the system, and the interactions that take place between components. The model should be able to be validated to show that it gives rise to the desired POI, and if applicable, under what parameter ranges.

## Conclusion

We have outlined a role for the AIS practitioner in defining design principles that capture particular properties of the immune system. Such principles are free from immunological jargon and thus can easily be interpreted by engineers wishing to solve a problem. We believe this will increase the usage of immune-inspired solutions to engineering problems, through facilitating access to the subject by those unfamiliar

with the biological field, and secondly, by providing principles that are readily understood in terms of their computational properties.

### Abstract

Immunos 99 is a classification algorithm based upon the principles of Artificial Immune Systems (AIS). AIS algorithms can provide alternatives to classical techniques such as decision trees for classification tasks. Immunos 99 provides one alternative however the algorithm and implementations have some room for performance improvement. This paper discusses improvements made to Immunos 99 and its reference implementation to improve runtime performance. The new algorithm/implementation results in an approximate 40% reduction in run time on test data. The paper closes with a proposal for an implementation of the Immunos 99 algorithm that is suitable for use on map/reduce clusters.

### Introduction

The classification of large data sets is increasingly important in a wide variety of applications. Many classification techniques are available, with varying applicability. The need to apply classification techniques to large datasets has motivated research on improving the efficiency or running time of algorithms. For example the AIRS classifier (Watkins, Timmis, & Boggess, 2004) has been successfully parallelised, reducing execution time while retaining classification performance (Watkins & Timmis, 2004).

Our interest in the classification of large data sets relates to the automation of business process analysis. A business process is a set of activities that are required in a specific order, to provide a product or service. Efficient organisation of business processes is essential to the efficient running of the business itself. The data collected by monitoring of business processes is not clean, which limits the range of applicable classification techniques (Taylor, Leida, & Majeed, 2012). Techniques which are both resistant to noise in training data and applicable across a wide variety of input data are therefore of particular interest in this endeavour.

In initial small-scale experimentation on samples of poor quality data from real business processes, the Immunos 99 algorithm, proposed by Brownlee (Brownlee, 2005), showed promising performance. However the runtime performance of this (and other) classifier made its use infeasible for large data sets. Immunos 99 is a classification algorithm

inspired by the Immunos family, which incorporates additional immune-inspired techniques such as cell proliferation and hypermutation. A complete specification for Immunos 99 can be found in (Brownlee, 2005, Section 5). The only publicly-available implementation of the algorithm is a plugin for the Weka data mining toolkit (Hall et al., 2009; Brownlee, n.d.).

### Motivation & Experimental Environment

We are working on monitoring data for business processes relating to provision of service and customer interactions. The ability to predict and prevent the failure of business processes in these areas would enable organisations to perform more efficiently, achieving improved levels of customer service and customer satisfaction. There is little research on the automated analysis of such business processes, not least because of the poor quality of data available. However, if classification is to be useful industrially, it has to be achieved fast enough to allow timely intervention in failing business processes.

In small-scale trials, we tested a range of classifiers, seeking effective prediction of the outcome of a business process is considered; since the business process outcome can be only *SUCCESS* or *FAILURE*, based on some business condition, the problem is a two-class classification task. We find that Immunos 99 can be trained to handle classification of the real data, which is noisy and of low quality.

We next trained Immunos 99 with a typical dataset from BT process monitoring. The proprietary dataset comprises observations on 65,000 business processes, over 46 variables; 74% of the business processes were identified as belonging to the class *SUCCESS*, and the remaining 26% were classified as *FAILURE*. The trial performed 10-fold cross-validation on the dataset, for each classifier under test. However, the execution of the training runs was infeasibly long, with typical executions taking around 40 hours to complete classification of a day's test data.

Since Immunos 99 was the most successful classification technique in small-scale trials, we decided to improve the implementation of the algorithm, exploiting multi-

threading, with the goal of reducing execution time. What constitutes an appropriate execution time in this work is dependent on business context – the execution must complete in time to be able to intervene in a business process that may take hours, or may take weeks to complete. Our initial goal was to reduce execution time so that training on one day’s data takes hours rather than days.

The purpose and goal of our work on the Immunos 99 algorithm is to enable training and classification of large, noisy data sets, at an appropriate speed for the business context. We do *not* include rigorous algorithmic analysis, as this is not appropriate for our business context.

The improvements discussed here have been tested across large proprietary datasets, and the improvement in execution time has been shown throughout. Results from one of the proprietary datasets is included, to show improvements in execution time are achievable on the real datasets. However, owing to the proprietary nature of the data, the paper illustrates performance by application to a public dataset (Section ), allowing detailed discussion and analysis, as well as presentation of reproducible results.

### Analysing the Original Immunos 99

Immunos 99 is an immune-inspired classifier originally described by Brownlee (Brownlee, 2005) (Algorithm 1). It utilises a number of immune system features, and analogues of immune system components in its design. In an immune system, an antigen is something that provokes a response from the immune system; in this case, an antigen is analogous to an observation from the input data. In an immune system, the B-cells are recognisers that bind to specific antigens with a particular affinity; here the analogy is of recognisers with an affinity represented as a numerical value.

Here, we use complexity functions to reason about relative execution times, independent of implementation variations. Assuming that each operation in the function takes 1 unit of time, the estimated runtime for a sequential execution of the algorithm is equal to its complexity. Changes to the defined functions to account for the expected reduction in runtime caused by the application of multi-threading and parallelism are discussed in the following section. The complexity functions are derived from examination of the original implementation of the algorithm in (Brownlee, n.d.).

To calculate the complexity function, let  $g$  represent the number of generations to use and  $n$  represent the number of observations in the input data, which is also the size of the initial B-cell pool. The algorithm performs  $g * n^2$  affinity calculations. After each B-cell has been exposed and the affinity calculated, fitness is determined by the B-cell’s rank position in the B-cell pool. To determine the rank position requires a sort operation, of complexity in the order of  $O(n \log(n))$ .

To train the algorithm,  $n$  is the size of the training set. There are  $c$  classification classes, and a total of  $a$  antibodies

---

**Algorithm 1:** Original Immunos 99 Training Algorithm, from (Brownlee, 2005)

---

```

1 Divide data into antigen groups (by classification label)
2 foreach group do
3   Create initial B-Cell population
4   foreach generation (to parameter limit) do
5     Expose all B-cells to all antigens from all groups
6     Calculate fitness scoring
7     Perform population pruning
8     Perform affinity maturation
9     Insert randomly selected antigens of the same group
10  end
11 end
12 Perform final pruning for each B-cell population
13 return the final B-cell population as the classifier

```

---

ies in pool, where  $a_c$  is the number of antibodies for class  $c$ . The approximate complexity of the training phase of Immunos 99 is formed of the three parts: the initial generation of antibodies in equation 1 (line 3); the generation and mutation phase in equation 2 (lines 5-9); and the final pruning phase in 3 (line 12). The complexity of the overall training implementation is the sum of the three phases – the function shows a typical quadratic relationship, plotted against size.

$$2n + a + c \quad (1)$$

$$g(c(a_c + n(7a_c + 2(a_c \log(a_c)))))) \quad (2)$$

$$c(a_c + n(3a_c + a_c \log(a_c))) \quad (3)$$

### Parallelising the Algorithm

A number of changes have been made, to improve training times for the Immunos 99 algorithm. These improvements fall into 2 categories, first partial threading of the algorithm itself, and second changes to the Java implementation (published in (Brownlee, n.d.)). Partial threading is introduced using the Fork-Join paradigm which is supported by the core Java library in Java 7.

The first opportunity for parallelism, training of each group of B-cells in parallel, is identified by Brownlee (Brownlee, 2005), but not included in the Weka implementation.

The most time consuming part of the algorithm is the affinity calculations across all antibodies and all antigens. Each affinity calculation (the affinity of one antigen to one B-Cell) is independent of all the other affinity calculations. This is a significant opportunity for further parallelism to be introduced. The nested loops running the affinity calculations in series (lines 5-6 of Algorithm 1) can be replaced with a construct that distributes the individual calculations

to the available thread pool, and then collects the results as each thread completes. Once all calculations are complete, the normal sequence of the algorithm is resumed.

An example of the fork-join construct is shown in figure 1. The modified algorithm is summarised in Algorithm 2. The fork-join construct is used for the blocks between lines 7-13 and lines 22-30, with the worker threads performing lines 10 and 25 only.

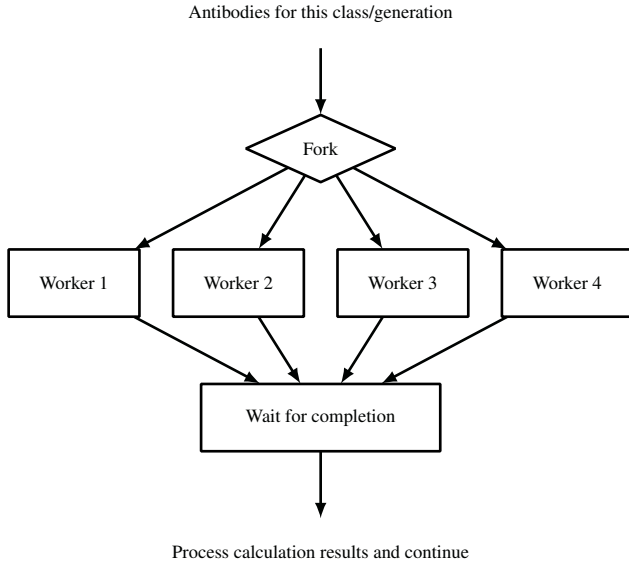

Figure 1: Example fork-Join construct for antibody affinity calculation

The parallelised algorithm uses the same number of operations to train the classifier as the original Immunos 99 algorithm, so the complexity function is the same. If we assume that each computation takes a single time unit, the expected runtime of the modified algorithm is reduced, since affinity calculations occur simultaneously. For the three phases of the algorithm described for the original, and a thread pool of size  $t$ , the estimated runtime of the initial setup phase is unchanged (equation 1). The estimated runtime of the modified generation and mutation phase, and of the modified final pruning phase are given by equations 5 and 4, respectively. The runtime of the algorithm is primarily influenced by the number of classes in the training data (since each group of antibodies can be trained in parallel with enough threads) and by the number of execution threads available (reducing the time required to complete the affinity calculations by allowing more to be performed in parallel).

$$g\left(\frac{a_c + n\left(\frac{a_c}{t} + (6a_c) + 2(a_c \log(a_c))\right)}{\min(c, t)}\right) \quad (4)$$

$$c(a_c + n(2(\frac{a_c}{t}) + a_c + a_c \log(a_c))) \quad (5)$$

Figure 2 shows the effect of additional threads on the complexity of the algorithm for a hypothetical 4 class prob-

---

#### Algorithm 2: Parallelised Immunos 99 algorithm

---

```

1 Create the thread pool,  $p$ 
2 Divide data into antigen groups (by classification label)
3 foreach group do
4   Create initial B-Cell population
5   foreach generation (to parameter limit) do
6     begin Expose all B-cells to all antigens from all groups
7       foreach Antigen,  $ag$ , in the training set do
8         foreach Antibody,  $ab$  in the generation do
9           begin on a thread from  $p$ 
10            Calculate the affinity between  $ag$  and  $ab$ 
11          end
12        end
13      end
14    end
15    Calculate fitness scoring
16    Perform population pruning
17    Perform affinity maturation
18    Insert randomly selected antigens of the same group
19  end
20 end
21 begin final pruning for each B-cell population
22 foreach Antigen,  $ag$ , in the training set do
23   foreach Antibody,  $ab$  in the last generation do
24     begin on a thread from  $p$ 
25       Calculate the affinity between  $ag$  and  $ab$ 
26     end
27   end
28    $ab_{best} = ab$  with best affinity to  $ag$ 
29   increment score of  $ab_{best}$ 
30 end
31 Prune antibodies with score below threshold
32 end
33 return the final B-cell population as the classifier

```

---

lem – using more than  $c$  threads has only a small additional benefit. Figure 3 illustrates the effect of increasing the number of classes, where the thread pool size is equal to the number of classes.

#### Other Parallelisation: the AIRS Approach

Watkins, Timmis, and Boggess report parallelisation of the AIRS algorithm (Watkins, Timmis, & Boggess, 2004; Watkins & Timmis, 2004), which we look to for inspiration. In the AIRS parallelisation the training data is partitioned and sent to threads which train independently before merging the resulting memory cells into a single pool for classification. The AIRS approach is more pervasively parallel than

Figure 2: Effect of additional threads on the estimated run-time of modified Immunos 99 on 4 class data.

the Immunos 99 parallelisation, as it distributes large, intensive, independent units of work. In contrast, the Immunos 99 parallelisation approach attempts to gain the largest increase in performance possible without extensive redesign of the original code – the modified Immunos 99 implementation only minimally changes the serial version to distribute the large number of computationally simple affinity calculations.

### Reducing Implementation Inefficiencies

The original implementation of the Immunos 99 algorithm is part of the Weka Classification Algorithms project on SourceForge (Brownlee, n.d.). We analysed the execution of the original Weka code using the VisualVM profiler (Oracle Corporation, n.d.). VisualVM identifies the hot spots in the code where improvements are most likely to have an impact. The profiler analysis was used both to guide the algorithmic changes in the previous section and, in conjunction with code reviews, to identify inefficiencies in the use of Java and its libraries. These implementation-specific improvements affect the runtime of the Immunos 99 modified algorithm, but are not factored into the general complexity analysis in Sections and , as they pertain to specific versions of the implementation, Java library and virtual machine.

A significant time overhead in the Weka implementation is the use of array copy operations. For instance, each time the algorithm calls `Collections.sort` from the Java library sorting functions, the collection is copied into a temporary array, sorted, and copied back, rewriting the original collection. We reduce the time to sort a collection by

Figure 3: Impact of number of classes on estimated runtime of modified Immunos 99 (with  $t = c$ ).

implementing a sort function that directly modifies the array behind each collection without any copying. A simpler modification to reduce copying is achieved by refactoring the Weka code to avoid unnecessary use of methods that rely on copying, such as `Instance.toDoubleArray()`.

The profiler analysis showed extensive use of `LinkedList` objects. `LinkedLists` are inefficient when used in conjunction with random access operations, as in the original code, since every index request requires traversal of the list (average complexity  $O(n/2)$ ). To improve efficiency, the `LinkedList` objects were replaced with `ArrayList` objects, which provide the same interface but have complexity of  $O(1)$  access to contents.

A review of the logic of the Weka implementation revealed an inefficiency in the final pruning step (Algorithm 1 line 7). At this step, only the antibody with the best affinity is required, so it is unnecessary to sort all the antibodies by affinity. By replacing a call to `Collections.sort` with a call to `Collections.min`, the complexity is reduced from  $O(n \log(n))$  (for sorting) to  $O(n)$  (to scan the collection).

### Experimental Results

We illustrate the difference in execution time between the original and modified implementations using the *Chess (King-Rook vs. King-Knight) Data Set* (kr-kk) from the UCI machine learning repository (Frank & Asuncion, 2010). Each test is a 10-fold cross validation of the kr-kk dataset, which is repeated 10 times, with the time for each run recorded. Tests are performed on an otherwise-idle Win-

Figure 4: Box plots showing execution times and accuracy for 10-fold cross-validation of each implementation on the chess data set

dows Server 2008 box with 16 Cores (4x Intel Xeon E7340 CPUs) and 32GB of RAM. Tests are run under the 64-bit Java 7 JDK (version 1.7.0-b147).

Figure 4 shows the time and classification performance of the implementations. The box plots show the median value as the centre bar; the outer limits of the box are the first and third quartiles, and whiskers show the highest and lowest value within  $1.5 * InterquartileRange$  of the box edge. Any outliers are shown as points.

The results for execution time (upper plot in Figure 4) shows that the improved algorithm has a mean execution time that is approximately 58% of the execution time for the original. Both implementations exhibit very low levels of variation in execution time. The outlier in the plot for the modified algorithm is thought to be due to the influence of the operating system scheduler on the server performing the tests.

The lack of overlap between the result ranges of the two

Figure 5: Box plots showing execution times and accuracy for 10-fold cross-validation of each implementation on the proprietary data set

implementations indicates a significant improvement in execution time with the modified implementation. A non-parametric Mann-Whitney U test for significance was performed, with  $H_0$  of no significant difference between the performance of the original and modified implementations. The test p-value is 0.0001806, so  $H_0$  is rejected with greater than 99% confidence.

To increase confidence that the classification ability of the algorithm has not been compromised by the modifications, the overall classification accuracy was also recorded for the 10 runs (lower plot in Figure 4). In the results, the modified algorithm has a slightly lower median accuracy, but less variation in classification performance than in the original implementation. Performing the Mann-Whitney U test for significance, with  $H_0$  that there is no significant difference between the performance of each algorithm yields a p-value of 0.6305 so  $H_0$  is accepted.

In the motivation for this work (Section ), we describe

the training phase execution of the original algorithm on a proprietary dataset, which took in the order of 40 hours to complete. Performance of the modified algorithm was also tested on this proprietary dataset. The experimental setup was identical to that for the kr-kk dataset. The mean execution time was reduced from 38.86744 hours for the unmodified algorithm to 3.29218 hours for the modified algorithm. A Mann Whitney U Test for significance was again performed, with  $H_0$  that the execution time for the two implementations is the same. The p-value of 0.00001083 determines that  $H_0$  is rejected with greater than 99% confidence. The mean accuracy of the algorithms is almost identical: 60.274% and 60.276% for the unmodified and modified implementations, respectively (Mann Whitney U Test p-value of 0.9092). The results (following the same format as before) are plotted in figure 5.

The results are in line with expectation: the quadratic complexity of the Immunos 99 algorithm means that performance gains from the modified implementation should be higher for larger datasets. We have also informally observed increased improvements for larger datasets in other work on proprietary datasets.

### Further Work: Proposed Map-Reduce Implementation

In working on the Immunos 99 algorithm, it became apparent that a map-reduce variant of Immunos 99 would support massively-parallel execution. This should lead to feasible training times for very large datasets. The outline is presented here as an opportunity for further work.

Map-reduce (Dean & Ghemawat, 2008; The Apache Software Foundation, n.d.) allows tasks to be broken down into an arrangement of *map* and *reduce* tasks. Map tasks are responsible for splitting the incoming data into chunks that can be independently processed. Reduce tasks are responsible for processing a chunk of data and then returning a result to the next task in the chain. The most time consuming part of the Immunos 99 algorithm (exposing all B-cells to all antigens) could leverage these constructs as follows.

1. Scoring of each antibody within a generation can be performed independently of any other antibody.
2. Each antigen/antibody affinity comparison used to calculate the antibody score can be mapped out as a separate task.
3. Ranking the antibodies by affinity for scoring could be a subsequent reduce task that merges the antibody scores into a sorted list for the calculation (cf. merge sort).
4. Rank scoring of the antibodies for each instance can be done as a reduce task on the sorted antibody scores.
5. Final pruning and other finalising tasks can be performed in serial by a final reduce task.

The final pruning step could be implemented using a similar series of map and reduce tasks, which would further reduce execution time.

The map-reduce approach would allow a refactoring that can efficiently exploit a large number of compute resources to process in a much shorter time than either the original implementation in Section , or the improved variant in Section . A caveat to this is that the time spent administering and distributing the map and reduce tasks over a compute cluster is not insignificant, so for smaller datasets the single machine approach from Section is likely to be faster.

### Conclusion

This paper has assessed the practical performance of the Immunos 99 classification algorithm (Brownlee, 2005), considering some performance deficiencies of the algorithm and its publicly-available implementation (Brownlee, n.d.). We present modifications to the existing source code that enable Immunos 99 training to run in an acceptable time (according to the business context) on large, noisy datasets, by effective exploitation of multi-core processors are discussed. We outline additional modifications using the map-reduce paradigm (Dean & Ghemawat, 2008; The Apache Software Foundation, n.d.) which have the potential to support massively-parallel execution.

# Modelling the Migration and Maturation of Dendritic Cells for Automatic Optimization of Complex Engineering Problems

N.M.Y. Lee<sup>1</sup> and H.Y.K. Lau<sup>2</sup>

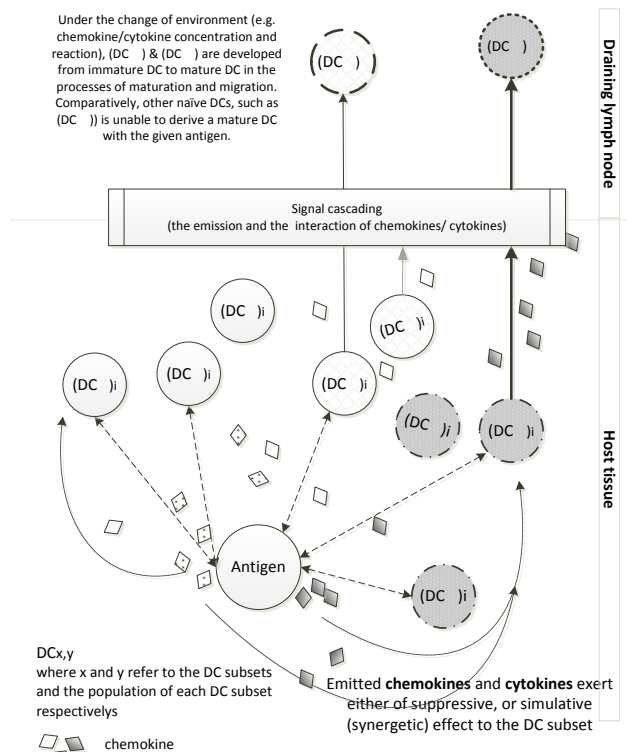

<sup>1,2</sup> The University of Hong Kong  
[myleenicole@gradaute.hku.hk](mailto:myleenicole@gradaute.hku.hk), [hyklau@hku.hk](mailto:hyklau@hku.hk)

## Abstract

The metaphor of Migration and Maturation of Dendritic Cells (DCs), in particular, the induced signal pathways to the change of the immunogenic functions of DCs (Martin-Fontecha, Lanzavecchis & Sallusto, 2009) provides important features for the development of the proposed DC-inspired optimization algorithm. Specifically, the quantified capability and behavioral change of DCs (Callard, George & Stark, 1999) of the classical DC models (Caetano Reis, 2006), namely, (i) ontogeny of DC, (ii) the selectively up-regulation of markers (of DC subsets), (iii) the level of threat (of the antigen), (iv) production of chemokine and cytokine, (v) transcription factors, and (vi) the effector functions of DCs underpin a highly autonomous control mechanism for the evolution of the optimal solution(s).

In the proposed autonomous optimization framework, a multi-agent system is developed as described in (Lee & Lau, 2012) incorporating the following DC-inspired philosophies,

- Compartmental interaction and communication of agents.
- Potential threat of solutions is scaled as DCs perform in the host tissue, as well as the measurement of the fitness of the solution(s).
- Synergetic signal cascading (i.e. cytokine production) (Ricart et al., 2011) is adopted to facilitate the solution development process with self-governing characteristic.
- Effector functions are defined to gauge the quality of solution during the solution development (for example, to recruit more DC subsets and re-generating more candidate solutions as depicted in Fig.1).

**Fig. 1.** Schematic diagram of the interactions between DC subsets and chemokine in maturation and migration where DCs are represented by (DC<sub>x,y</sub>)<sub>i</sub> and (DC<sub>x,y</sub>)<sub>m</sub>

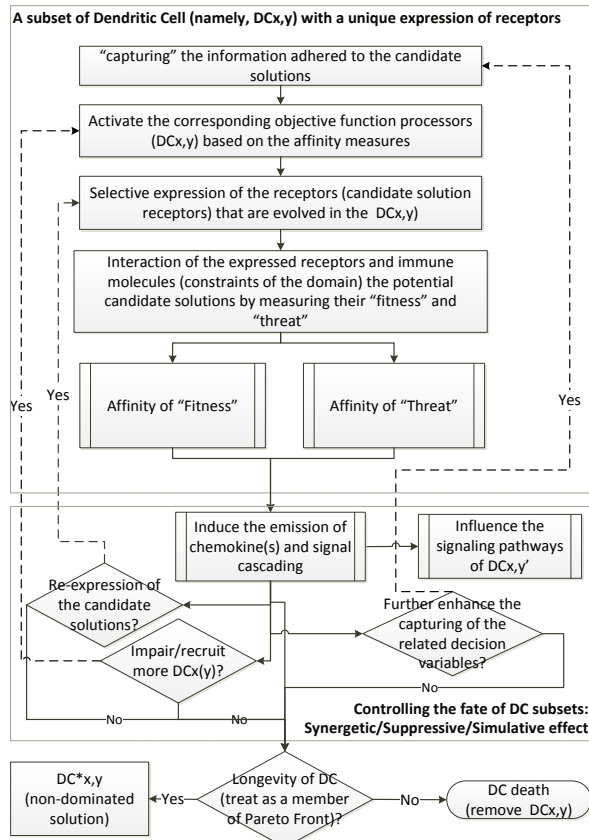

In the proposed framework (as depicted in Fig. 2), each artificial DC uptakes the characteristics of an antigen (or a permutation) for assessing the level of “fitness” and “threat” of the solution, which are critical to the signal production and forthcoming pathways. Similar to the classical optimization algorithm, “fitness” refers to the optimality for the given objective functions. Whilst the “threat” introduced in the proposed DC-inspired optimization algorithm is quantified by the virulence factors (to the domains), number of iterations or number of replications. These quantified “threat” perhaps ruining the quality of solutions instead of the measurement of “fitness”.

Further enhancing the autonomous control of the proposed framework, immunological signal cascading is adopted. Biologically, signal cascading is represented by a highly dynamic and complex network of immunological signals, namely, chemokines and cytokines. They are predominantly emitted based on the quantified “threat” and “fitness” as abovementioned. The emitted signals and their interactions will further stimulate/suppress the production of chemokine and cytokine. For each of produced signals, it has a specific role in governing the behaviors of the artificial DC subsets, particularly aims at presenting the best for the activation of T-cell. With the inspirations of these immuno-features, a metaphor is anticipated for evolving the optimal solution(s) in the optimization problem. Primarily, the following immunological effector functions are implemented in the proposed DC-based optimization framework,

- Ontology – e.g. recruiting new populations (of artificial DC subsets).
- Phenotype – e.g. changing the permutations (re-capturing the characteristics of the given problem).

- Population – e.g. the death rate of artificial DC subsets, and the rate of proliferation.
- Migratory behavior.

By modeling DCs' capabilities and behaviors changes in maturation and migration, namely, the quantified level of "threat" and a self-regulated metaphor, the optimal solutions will be resulted. More importantly, the solutions generation can be specific and avoid premature converge which is observed in the classical optimization algorithms.

**Fig. 2.** Proposed automatic DC-mediated Cascading Framework for pursuing an optimal solution – For the attack, each DC subset (denoted by DC<sub>x,y</sub>) acts as a “decision maker” (or “controller”) is equipped with a distinct phenotype for gauging the threat of the candidate solutions (as antigens) based on (i) the emitted signals (as cytokines and chemokine), and (ii) their interactions with the corresponding receptors, and other immune molecules from the neighbouring DC subsets.

In parallel to the studies of classic DC maturation models, impact of the properties changes of “ontogeny” (Population subsets), “phenotype” and “effector” to solutions development are studied in the proposed DC-inspired optimization framework. More importantly, the study reveals some of the unexplored immuno-phenomenon and mechanisms through Matlab simulation.

## Abstract

Through the analysis of one-vs.-one, one-vs.-rest and the decision tree mechanism of binary support vector machine emotion classifiers, a method based on feature-driven hierarchical support vector machine is proposed for speech emotion recognition. For each layer, classifier used different feature parameters to drive its performance, and each emotion is subdivided layer by layer. This method did not rely entirely on the activity-valence dimensional emotion model, but relied on the type of emotion to distinguish. Furthermore, classifications are constructed by appropriate characteristic parameters ultimately. Experiments on the Chinese-speaker-dependent and Berlin-speaker-independent corpus reached conclusions as follows, Chinese-speaker-dependent recognition rate is relatively higher than Berlin-speaker-independent. feature-driven hierarchical support vector machine in the case driven by effective features improves the speech emotion recognition performance. Meanwhile applying the mean of the log-spectrum to this method can identify high-activity and low-activity emotion effectively.

Keywords: Feature-driven, Speech emotion recognition, Support vector machine (SVM), Hierarchical Classifier, Mean of the Log-Spectrum (MLS)

## 1. Introduction

Speech emotion recognition is not only used for human-computer interaction, but also applied in speech synthesis, artificial counseling, polygraph, telephone banking, driverless system and so on[1]. Nowadays, the field of emotion recognition is facing to huge challenges. The main difficulty [2] is that we could not extract a most effective universal phonetic feature for various kinds of emotion. Furthermore, one sentence may contain several kinds of emotions at the same time, and emotions may be associated with just parts of a sentence. There is no clear boundary for each complex emotion. Sometimes even humans are not capable of distinguishing them. Moreover, their cultural backgrounds and the environments also affect the emotion expression. Speech emotion recognition is a hot research issue in natural computing area, some researchers and institutions have done many works for emotion recognition [3].

Emotion recognition system consists of three parts: the module for extracting feature parameters, the module for reducing feature parameters' dimensions and the module for emotion recognition. Most researchers mainly utilized prosody features [4-6] like pitch period, short time energy, duration of voice, and their relative statistics as feature parameters. Besides, MFCC (Mel Frequency Cepstrum Coefficient) was also used for emotion recognition. This coefficient has more information when it is extracted from voiced sound rather than from unvoiced sound. Yang[7] proposed a coordinate feature set based on music theory for emotion recognition. They considered that the acoustic and semantic features were useful for the recognition. Another problem in speech emotion recognition is how to reduce the dimensions of the features in order to simplify the calculation. There were several common ways to do it: Sequential Floating Forward Selection (SFFS), Forward Feature Selection (FFS), Backward Feature Selection (BFS), Principal Component Analysis (PCA) and Linear Discriminate Analysis (LDA). After the simplified features obtained, we needed to build the effective classifiers. In 1990s, most of the emotional models were built on Maximum Likelihood Bayes (MLB) and Linear Discriminant Classification (LDC). Now, there are much more kinds of emotional models being used for emotion classification, like Hidden Markov Model (HMM), Gaussian Mixture Models (GMM), Artificial Neural Network (ANN), Support Vector Machine (SVM) etc. [8], and sometimes we use multiple methods simultaneously. However, we cannot know which classifier is the best at the current time.

SVM stemmed from statistical learning theory proposed by Vapnik and others, as a classifier. SVM could yield good results even from small test samples. So it was widely used for speech emotional recognition. Because of the Structural Risk Minimization, SVM classifier usually had better performance than others [9]. In this paper, an improved method based on feature driven is proposed in order to perfect speech emotional recognition performance. Feature-driven hierarchical SVM does not completely depend on the emotion dimensional model of activation-valence, and it adjusts the feature parameters of each layer gradually according to the property recognized by lots of experiments.

This paper is organized as follows. In section 2, several speech corpora are described, and then Chinese Speaker-dependent and Berlin speaker-independent Speech Corpus are used in this paper. In section 3, three kinds of binary SVM emotion classifications are discussed for a multi-category classification problem of Speech emotion recognition. In section 4, Hierarchical SVM emotion recognition method based on feature-driven is proposed to improve the performance of Speech emotion recognition. We extract six feature parameter classes based on prosody affective features and acoustic affective features to achieve the hierarchical SVM classifiers analysis. Experimental comparison between 4 kinds of hierarchical methods and some analysis for improved the parameters in speech feature driven method are discussed, and compared in section 5. Finally, conclusions are summarized in section 6. The page limit is 8 pages for a full paper. Your submission must be converted to Portable Document Format (PDF). Please be sure to use highest portability and quality options. Papers that significantly deviate from these instructions will not be included.

## 2. Several binary SVM classifications

Support vector machines(SVMs) are one of supervised learning models with associated learning algorithms. Speech emotion recognition of is a multi-category classification problem, here it is converted to binary classification problem to solve one by one, the state-of-the-art including:

### 2.1 One-Versus-One binary SVM

The hyper planes of binary SVM are built from any two of all categories, so the number of binary SVM classifiers is  $k*(k-1)/2$ . Here 'max-wins' voting method is used, for One-Versus-One voting strategy, the  $k*(k-1)/2$  binary SVM classifiers are trained in parallel, For example, category  $i$  and category  $j$  trains with classifier  $C_{ij}$ ,  $C_{ij}$  decides whether sample  $x$  belong to category  $i$  or category  $j$ . Therefore the number of  $i$  category votes adds one, otherwise  $j$ 's number of votes adds one. When the process is over, the category with the most voters is the right category that the sample belongs to. The structure of One-Versus-One binary SVM is shown in figure 1. Here 1-5 are set to represent 5 emotion categories of 2 speech corpora, so 10 classifiers are trained. From the process of category, we know that this method is less effective while the number of the classifiers increases, which will cause the decision speed more slowly.

Figure 1: One-Versus-One 'max-wins' voting SVM

### 2.2 One-Versus-The-Rest binary SVM

One-Versus-The-Rest binary SVM only builds  $k$  SVMs, each SVM classifier recognizes one category from all the other categories. The unbalanced decision tree combines the One-Versus-The-Rest with right branch, and it just needs to train  $(k-1)$  classifiers, the number of classifiers is less than them in one-versus-one method. Figure 2 shows the structure of this method, the recognized emotion should be the easiest

to be distinguished on first layer. Chinese Speaker-dependent speech corpus is used, furthermore anger is chosen on the first layer. For instance, 1 represents anger, 2 represents sadness, 3 represents happiness, 4 represents neutral and 5 represents amazement.

Figure 2: One-Versus-The-Rest unbalanced binary tree SVM

### 2.3 SVM decision Tree Mechanism

The classification error may occurs on any layer of these nodes, and it will spread to all the successor nodes, to this problem, DAG (directed acyclic graph) is proposed by Platt and others [11]. There are  $k*(k-1)/2$  internal nodes,  $k$  branches, each node is a SVM binary classifier. For each test sample, each node's binary decision determines the path of the next decision from the root node. Figure 3 demonstrates the five categories' directed acyclic graph. Whatever the emotion of the test sample is, it will always reach to the bottom of the classifiers[12]. Here, the result is right when every classifier's result is right, but because each binary classifier just handles 2 different emotions, the training is simple and effective. where 1 represents anger, 2 represents sadness, 3 represents happiness, 4 represents neutral and 5 represents amazement in figure 3.

Figure 3: Directed acyclic graph SVM

## 3 Extracting the speech emotion characteristic parameters

Six kinds of feature parameters are extracted to study the hierarchical SVM classifiers based on prosody affective features and acoustic affective features.

### 3.1 Prosody affective features

Prosody affective feature usually includes intensity, length or duration, pitch, accent, tone, intonation and rhythm.

**Short time energy and short time amplitude:**

$$Energy(n) = \sum_{m=0}^{M-1} |S_n(m)|^2, n=0,1,\dots,N-1 \quad (1)$$

Where  $S_n$  is the  $n$ th frame after enframing and windowing,  $N$  is the number of frames,  $M$  is the length of frame. From figure 4, we know that different emotion has different short time energy change, the same is true for short time amplitude.

(a) Sadness in Chinese speaker-dependent

(b) Anger in Chinese speaker-dependent

Figure 4. Voice activity detection using double threshold comparison method

**Short time zero-crossing rate:**

$$Z_n = \sum_{m=-\infty}^{\infty} |\text{sgn}[x(n)] - \text{sgn}[x(n-1)]| \cdot w(n-m) \quad (2)$$

In addition, short time zero-crossing rate combined with short time energy is used in hunting for starting point and end point of the sound, Figure 4 demonstrates this problem, when make final decision, the threshold is needed to set in real situation.

**Pitch period:**

$$\tau_N(k) = \frac{1}{N} \sum_{n=0}^{N-k-1} x(n)x(n+k), 0 \leq k \leq M_o - 1 \quad (3)$$

Where  $t_n$  is the value of autocorrelation function,  $x(n)$  is the recognized voice signal,  $k$  is the delay time,  $M_o$  is the number of the autocorrelation which is calculated in [13]. After getting the autocorrelation function and detecting its peak, we can get pitch period. Figure 5 are shown for Chinese Speaker-dependent speech corpus's pitch period of the same sentence expressed by anger, sadness, neutral and amazement

respectively, and the rate of change in anger and amazement is larger than in sadness and neutral, at the end of the sadness's pitch period envelop curve is cocking up.

Figure 5. The pitch period of four kind emotions for Chinese speaker-dependent

### 3.2 Acoustic affective features

Acoustic affective features are generally the feature of tone and speech spectrum.

**Formant:**

$$P(w) = 20 \log \left( \frac{1}{|1 + \sum_{k=1}^p a_k e^{-j\omega k}|^2} \right), k=1, 2, \dots, p \quad (4)$$

Levinson-Durbin method is used to calculate the linear prediction coefficient  $a_k()$ . The LPC spectrum are calculated by formula (4), only the first 3 formants are extracted.

**MFCCs:**

The extracting processes of Mel Frequency Cepstral Coefficients (MFCCs) are shown in figure 6.

Figure 6: The MFCC extracting process

**Mean of log power spectrum (MLS):**

MLS is calculated by each frame's of one sentence, which is mainly used to convert time domain signal to frequency domain signal. Thus the average of MLS are calculated as showed in formula (5), where  $k$  is spectrum bandwidth,  $N_l$  is the  $l$ th class emotion's utterance number,  $v_d(n, k)$  is the discrete Fourier transformation for the  $n$ th frame of signal  $i$ , the range of  $k$ 's bandwidth is between 0 to 2000Hz.

(a) The average of the log-spectrum for Chinese speaker-dependent

(b) The average of the log-spectrum for Berlin speaker-independent.

Figure 7: The average of the log-spectrum

$$S_i(k) = \frac{1}{N_i} \sum_{i=1}^N \frac{1}{N_i} \sum_{n=1}^N \log |v_{ii}(n, k)| \quad (5)$$

Figure 7 showed the average of the log-spectrum arranged by the similarity of spectrum. (a) is the 5 categories distributed situations of Chinese speaker-dependent. We can see that the MLS peak of anger, happiness concentrated to 400Hz, while the MLS peak of sadness and neutral concentrate to 200 to 250 HZ, MLS envelope curves are similar with each other, especially between high-activity and non-high-activity speech. (b) is the distributed situations of the log power spectrum mean of Berlin speaker-independent. They have similar envelope curves as they are both high-activity emotion. The MLS peak is also concentrated to 400Hz, while sadness, neutral and boredom are concentrated between 100 to 250 Hz. Now, six kinds of parameters and its different dimensions feature derivatives are extracted as showed in table 1.

Table 1: 247 dimensions global feature parameters

| Basic feature parameters        | statistical characteristic                                                                                                  | feature dimens ions |
|---------------------------------|-----------------------------------------------------------------------------------------------------------------------------|---------------------|
| short time energy and amplitude | Mean, standard deviation, minimum, maximum, dynamic range, mean of first difference, standard deviation of first difference | 14                  |
| short time zero crossing-rate   | Mean, standard deviation, minimum, maximum, dynamic range, mean of first difference, standard deviation of first difference | 7                   |
| pitch period                    | Mean, standard deviation, minimum, maximum, dynamic range, mean of first difference, standard deviation of first difference | 7                   |
| MFCC and its first difference   | Mean, standard deviation, minimum, maximum, dynamic range, mean of first difference, standard deviation of first difference | 168                 |
| First three formants            | Mean, standard deviation, minimum, maximum, dynamic range, mean of first difference, standard deviation of first difference | 21                  |
| 30 dimensions MLS               | mean                                                                                                                        | 30                  |

### 3.3 Reducing dimensions of feature vector

The more dimensions the feature vector has, the more information it contains. However, the calculated complex also greatly increases with the dimensions increases. When the number of vector dimensions exceeds a certain limit, dimension disaster [14] would appear. Therefore, feature selection in broad definition is one kind of mapping transformation from the high-dimensional vector to low-dimensional vector for the sake of reducing dimensions. For literature [15], principal component analysis (PCA) is contributed for reducing dimensions, when PCA is applied to classifiers. it not only reduces calculated quantity, but also eliminates some interference factors. Here, select several characteristic vectors as a main component vectors that correspond to the first  $k$  characteristic value, and  $d$  is the vector dimensions, we set  $k/d$  equals to 0.95, so the number of feature vector's dimensions are reduced from 247 to 31 using PCA in this paper.

### 4. Hierarchical SVM emotion recognition method based on feature-driven

It is shown in Figure 4, A feature-driven hierarchical SVM is proposed for emotion recognition, which demonstrates the structure of this method. In this paper, five kinds of emotions are subdivided for three layers. Especially, Feature-driven hierarchical SVM does not completely depend on the emotion dimensional model of activation-valence, and it adjusts the feature parameters of each layer gradually according to the property recognized by lots of experiments and experience. This feature-driven method is similar with unbalanced decision tree, however, the number of hierarchical layers decreases. A feature-driven hierarchical SVM is strict to each classifier of each layer, generally, we set the two easiest distinguished main categories as the first layer. Therefore, the performance of each classifier of each layer should be well enough to guarantee test samples correctly before it enters the next layer. Meanwhile, linear kernel function is utilized for hierarchical SVM based on feature-driven in this paper.

Figure 8: Feature-driven hierarchical SVM

In figure 8, 1 represents anger, 2 represents sadness, 3 represents happiness, 4 represents neutral and 5 represents amazement. The structural parameters are as following for Chinese Speaker-dependent speech corpus. Here, (1) Classifier C1 distinguishes anger, happiness and amazing emotion from sadness, neutral emotion. The feature parameters are the combination of short time energy, short time amplitude, short time zero-crossing rate, pitch period, and MLS (Mean of the Log-Spectrum). (2) Classifier C21 distinguishes sadness from neutral. In addition, the feature parameters of MFCC and formant are the combination.

(3) Classifier C2h distinguishes anger from happiness and amazement. Therefore, parameters includes short time energy, short time amplitude, pitch period, short time zero-crossing rate, mean value of 12 dimensions MFCC and formant combine the feature parameter.

(4) Classifier C3 distinguishes happiness from amazement. The feature parameter is all the feature parameters of C2h combined with MLS.

In the Berlin Speaker-independent speech corpus: 1 represents anger, 2 represents neutral, 3 represents happiness and 4 represents boredom. The structural parameters of Berlin Speaker-independent speech corpus follows. Here

(1) Classifier C1 distinguishes sadness, neutral and boredom from anger and happiness. The feature parameters of short time energy, short time amplitude, pitch period, short time zero-crossing rate and MLS (Mean of the Log-Spectrum) are the combination.

(2) Classifier C21 distinguishes anger from happiness. The feature parameters are the combination with short time energy, short time amplitude, pitch period, short time zero-crossing rate, MLS, and the mean of MFCC.

(3) Classifier C2h distinguishes sadness from neutral and boredom. The feature parameters are the combination of short time energy, short time amplitude, pitch period, short time zero-crossing rate, MFCC and formant.

(4) Classifier C3 distinguishes neutral from boredom, so the feature is the same as C2h.

## 5 Experimental test and result analysis

The orthogonal method is adopted to ensure the independent of each training and test samples. For the experimental process, we choose 50 sentences for each emotion, training samples using 30 of them, test samples using the rest 20. 50 sentences are labeled with 1-50, and every 10 sentences as one group, then there are totally  $C_5^3=10$  situations in the combination of training samples and test samples. Therefore, the 10 independent experiments are conducted to reduce the effect of the unbalance in speech corpus.

### 5.1 Speech Corpus

Chinese Speaker-dependent and Berlin Speaker-independent Speech Corpus are selected for our experiments. The term of speaker-dependent indicates that all the speech come from one person, which means tones and pronunciation habits are all the same. The Chinese speech corpus records the voice of a woman and includes 5 types of emotions: anger, sadness, happiness, amazement and neutral. Each type of emotion has 50 sentences. The corpus is saved as .wav format with 16 kHz-16 bit resolution. The Berlin corpus [10] records the voice of five man and five women and includes seven types of emotions: happiness, sadness, anger, boredom, disgust, fear and neutral. The corpus is also saved as .wav format with 16 kHz -16 bit resolution.

### 5.2 Comparison between Chinese Speaker-dependent and Berlin Speaker-independent speech corpus

We focus on the fallibility between anger, happiness and amazement in Chinese Speaker-dependent speech corpus, and

the fallibility between neutral and sadness. In Berlin Speaker-independent speech corpus, the anger is hard to distinguish from happiness. Meanwhile, the difference between sadness, neutral and boredom are also hard to detect. Therefore, we design the experiments to these two kinds of speech corpus using one versus one method and feature driven method respectively, the results are showed in figure 9. As the amazement in Chinese corpus and boredom in Berlin corpus is not on the same feature space in emotional model, so that just four kinds of emotions (anger, sadness, happiness and neutral) are compared in figure 9.

(a) 1vs1-voting mechanism

(b) feature-driven method

Figure 9: Comparison results of for Chinese and Berlin Corpus

From the results of figure 9, especially for feature driven SVM, we find that the recognition rate for speaker-dependent is obviously higher than for speaker-independent. This is mainly caused by different personal pronunciation habits. Hence, when emotional recognition for speaker-dependent is extended to speaker-independent, the effect of personal pronunciation should be eliminated in feature parameters. As is shown in figure 9, we also know that recognition rate for speaker-independent in one-versus-one mechanism does not decline evidently, which is shown that the 1vs1 recognition method is also available. Combined figure 9 (a) and (b), the emotion recognition rate for speaker-dependent in feature-driven method is almost higher than 1vs1-voting mechanism except for sadness. Meanwhile, the recognition rate for speaker-dependent is also higher than for speaker-independent. Those cause by two reasons. Firstly, there are more feature parameters fused in one-versus-one mechanism each layer which influences the recognition rate. Secondly,

the recognition feature parameters of each layer are more appropriate for Chinese vocal features than German in feature driven SVM.

### 5.3 Experimental comparison between four kinds of hierarchical methods

The recognition results of four kinds of hierarchical structure are shown in figure 10. The feature driven method not only keeps the recognition rate for anger, sadness and happiness, but also improves the recognition performance for neutral and amazement. it proves that feature driven method applied to Chinese Speaker-dependent person speech corpus is more effective.

From figure 10, the recognition rate of the one-versus-one mechanism is the highest among all four methods. In addition, recognition rates of unbalanced binary tree and directed acyclic graph are the almost same. The recognition performance of feature driven method is not satisfactory, especially for the sadness and happiness. Therefore, the main reason is that the Chinese pronunciation habit is different from Germany. As we all known that the pause time or silent segments in German is longer than it in Chinese, so the chosen parameters may fit for Chinese but not fit for German.

(a) Chinese Speaker-dependent corpus

(b) Berlin Speaker-independent corpus

Figure 10: Comparison between four kinds of methods

### 5.4 Experiments after improved the parameters in feature driven method of speech emotion recognition

Feature parameters in every layer of hierarchical SVM based on feature-driven are devised and modulated respectively for extracting those feature parameters fitter, meanwhile, for improving the recognition performance. The results after devised and modulated for parameters in feature driven method are showed in table 2.

Table 2: The parameters adjustment and the rate of error identification of feature-driven method

| classifier |                        | Chinese speaker-dependent corpus |                      | Berlin speaker-independent Corpus |                            |
|------------|------------------------|----------------------------------|----------------------|-----------------------------------|----------------------------|
| C1         | feature parameters     | ZEP                              | ZEP + MLS            | ZEP                               | ZEP + MLS                  |
|            | Error recognition rate | 8.7%                             | 6.9%                 | 10.3%                             | 8.1%                       |
| C2l        | feature parameters     | MFCC                             | MFCC + Formant       | MFCC                              | MFCC + ZEP & Formant & MLS |
|            | Error recognition rate | 24.34%                           | 22.25%               | 37.17%                            | 31.09%                     |
| C2h        | feature parameters     | ZEP & MFCC                       | ZEP & MFCC + Formant | ZEP & MFCC                        | ZEP & MFCC + Formant       |
|            | Error recognition rate | 18.57%                           | 16.49%               | 20.61%                            | 21.35%                     |
| C3         | feature parameters     | ZEP                              | ZEP & MFCC + Formant | ZEP                               | ZEP & MFCC + Formant & MLS |
|            | Error recognition rate | 19.34%                           | 12.96%               | 16.24%                            | 15.93%                     |

Here, ZEP represents the combination of short time energy, short time amplitude, pitch period and short zero-crossing rate. Here, given C1 as a instances for Chinese speech corpus to illustrate "Error recognition rate", when high valence emotion (anger, happiness and amazement) is judged to be low valence emotion (neutral, sadness), then it is considered error recognition, and vice versa. A computational method for another classifier is built through similar way.

(a) Chinese Speaker-dependent

(b) Berlin Speaker-independent

Figure 11: Results after improving parameters in Feature-driven methods

Figure 11 is the comparison between before improved and after improved feature driven method. Combining the figure 11 and table 2, we know that the recognition rate is greatly improved after importing the MLS feature parameter. Furthermore, the recognition rate of C21 and C2h classifiers in Chinese Speaker-dependent speech corpus improved after importing the formant, but the recognition rates of the two classifiers are adverse in Berlin Speaker-independent speech corpus. This indicates that a better feature parameters extracted is related to the type of language closely.

## 6. Conclusion

A new feature driven hierarchical SVM classifier is devised for emotion recognition. Here Chinese Speaker-dependent and Berlin Speaker-independent speech corpora are used for experimental study. Meanwhile, the mean of the log-spectrum (MLS) is particularly used to improve the feature driven SVM classifier. Since SVM isn't used to recognize multiple emotions directly. Therefore, we set ordinary binary SVM classifier as a contrast experiment to feature driven hierarchical SVM. Then we calculated the recognition rate respectively and analyzed the potential problems. However, the following problems still need further study. (1) All global feature parameters are extracted through the same statistical features, there may be conflict between statistical features and some feature's impact may be reduced when reducing dimensions through PCA. It is a research direction to use other methods such as SFS algorithm to reduce the dimensions. (2) How to extract effective feature parameters. The feature parameters extracted in this paper still can't separate anger, happiness from amazement and sadness from neutral very clearly. (3) Linear kernel function is utilized for binary SVM in this paper, for better performance, new kernel paper may be tried.

## Abstract

In evolutionary game theory, the main interest is normally on the investigation of how the distribution of strategies changes along time and whether an stable strategy arises. In this paper we compare the dynamics of two games in which three populations of agents interact: a three-player version of matching pennies and a game with several Nash equilibria. We do this comparison by three methods: continuous replicator dynamics, an evolutionary approach, and reinforcement learning. We show how the convergence depends on the nature of the underlying method used, as well as on the pace of adjustments by the agents.

## Introduction

In game theory (GT), one traditional explanation of equilibrium is that it results from an introspective analysis by the players when the rules of the game, the rationality of players, and the payoff functions are all common knowledge. It is well-known that both conceptually and empirically this argument has many problems. Just to mention one of them, in games with more than one equilibria, even if one assumes that players are able to coordinate their expectations using some selection procedure, it is not clear how such a procedure comes to be common knowledge (Fudenberg and Levine, 1998). Moreover, in the real world, individuals, as for instance animals, are not necessarily rational as assumed by the GT. Thus, in the context of evolutionary GT (EGT), alternative explanations focus on equilibrium arising as a long-run outcome of a process in which populations of animals interact over time.

In the next section, we briefly review some of these approaches. In particular, we note that one of the approaches, the replicator dynamics (RD), presents some problems related to its justification among populations of animals. In fact, there has been a great deal of questioning about why should one care about using the RD, since neither economic agents nor artificial agents (and actually not even monkeys) are genetically programmed to "play" certain behaviors. Thus a justification for the replicator could be that there is an underlying model of learning (by the agents) that gives rise to the dynamics.

Some alternatives have been proposed in this line. Fudenberg and Levine (1998) refer to two interpretation that relate to learning. The first is social learning, a kind of "asking around" model in which players can learn from others in the population. The second is a kind of satisficing-rather-than-optimizing learning process in which the probability of a determined strategy is proportional to the payoff difference with the mean expected payoff.

This second variant has been explored, among others, by Börgers and Sarin (1997); Tuyls et al. (2006), which are based on some kind of reinforcement learning at individual level. In particular, in the stimulus-response based approach of Börgers and Sarin, the reinforcement is proportional to the realized payoff (in their formulation, necessarily positive). Thus each strategy's probability increases by a factor that is computed by the current probability multiplied by the difference between the strategy's expected payoff and the expected payoff of the player's current mixed strategy. In the limit, it is shown that the trajectories of the stochastic process converges to the continuous RD. This is valid in a stationary environment. However, as noted by Börgers and Sarin and Fudenberg and Levine, this does not imply that the RD and the stochastic process have the same asymptotic behavior when the play of *both* players follow a stimulus-response learning approach. We remark that Fudenberg and Levine (1998) specifically mention a two agent or two population game, but the same is true (even more serious), when it comes to more.

The reasons for this difference are manifold. First, Börgers and Sarin's main assumption is "...an appropriately constructed continuous time limit", i.e., a gradual (very small) adjustment is made by players between two iterations of the game. This implies that the discrete learning model evolves stochastically, whereas the equations of the RD are deterministic. Also, there is the fact that players may be stuck in suboptimal strategies because they are all using a learning mechanism, thus turning the problem non-stationary. These facts have as consequences that other popular dynamics in game-theory as, e.g., best response dynamics, which involve instantaneous adjustments to best replies,

have difference in the asymptotic behavior. For example, in the matching pennies game, “discrete time replicator dynamics will cycle along expanding trajectories, but will not get absorbed by any pure strategy outcome” (Börgers and Sarin, 1997). In the battle of the sexes game, a learning approach which is not based on the gradual adaptation (such as best response) may prevent convergence to an equilibrium while the gradual adjustment of RD permits such convergence.

In summary, there are advantages and disadvantages in using the discussed approaches and interpretations, i.e., the continuous, analytical variant of RD, and learning and adaptation approaches such as best response, genetic algorithms, and stimulus-response based models. Besides, as we verify, not all adaptation methods do replicate the RD.

In this paper we aim at applying different approaches and compare their performance. Specifically, we use three of them: the analytical equations of the RD, a genetic based evolutionary approach, and reinforcement learning (here Q-learning). We remark that, as discussed in the next section, some learning approaches are not appropriate for this problem as they either consider perfect monitoring (observation of other individuals’ actions, as in Claus and Boutilier (1998)), or modeling of the opponent (as in fictitious play), or both. In our case this is not possible given the high number of individuals involved in the populations, and the unlikelihood of encounters happening frequently among the same individuals.

Further, we employ two games that are played by three populations of individuals and have been seen as metaphors for studying interactions in populations of individuals. The first is a three-person version of the matching pennies, due to Jordan (apud Fudenberg and Tirole (1991)). In this, as in the two-person original game, there is just a single Nash equilibrium (in mixed strategies). The second is due to B. O’Neill (apud Myerson (2002)), which pays a non-zero quantity to the players when exactly one of them select one of the two strategies. This game has eight Nash equilibria, four of which are in pure strategies, thus making the task of coordinating which equilibrium to select very hard for the individuals.

We are interested in the trajectory of a population of individuals with very little knowledge of the game. Indeed, they are only aware of the payoff or reward received, thus departing from the assumption of knowledge of payoff matrix and rationality being common knowledge, frequently made in GT. We show that, in the case of the three-player matching pennies, the evolutionary approach leads to the same result as the RD, namely to cycle, which means to the (unique) Nash equilibrium in mixed strategy. For the second game, it was possible to observe convergence to the Nash equilibria in pure strategies. In all cases, convergence depends on the rate of experimentation in the populations.

## Background and Related Work

### Evolutionary Game Theory

EGT investigates the relationship between individual and aggregate behaviors. Its inspiration comes from population genetics, where the focus is less on individual behavior and more on the aggregate population behavior. This shift from individual-level decision-making (eventually leading to user equilibrium), to dynamics of individuals interaction is in line with the increasing complexity in modern societies. There are many systems where we nowadays observe a tendency of a complex coupled decision-making process. Already in 1950, Nash saw this phenomenon, which he then called “mass-action interpretation”. Later, this focus on equilibria was criticized by J. Maynard Smith: “An obvious weakness of the game-theoretic approach to evolution is that it places great emphasis on equilibrium states ...” (Smith, 1982). Besides, J. Maynard Smith also dealt with the shift from individual to population level. Even if he borrowed some definitions from standard GT when he introduced the concept of evolutionary stable strategy (ESS) as a way to understand conflicts among animals, he had already noticed that “there are many situations ... in which an individual is, in effect, competing not against an individual opponent but against the population as a whole... Such cases can be described as ‘playing the field’ ...” (Smith, 1982).

Currently, this kind of modeling is called a population game, which models simultaneous interactions of a large number of simple individuals or agents distributed in a finite number of populations. Simple agents here mean that each has a (typically small) number of strategies to choose, causing a minor impact in other agents payoff. Despite this, the payoff of each agent is, as in the classical GT, conditioned by the distribution of strategies in each population. In EGT and population games, typically, one is not interested in constancy or equilibrium only. Rather, the major interest is on the dynamics of games. A population of decision-makers is considered, in which what is investigated is how the rate of the strategy profiles change as a response to the decisions made by all individuals in the population.

This idea that the composition of the population of individuals (and hence of strategies) in the next generations changes with time (in this case generations) suggests that we can see these individuals as replicators. The RD is based on gradual movement from worse to better strategies. One of the results of Börgers and Sarin is that in appropriately constructed continuous time limit, a stimulus-response based learning model converges to the continuous time version of the RD. They have proposed that such a continuous time limit is constructed so that each time interval sees many iterations of the game, and that the adjustments that the agents make between two iterations of the game are very small. This way the stochastic learning process becomes deterministic in the limit, thus replicating the system of differential equations which characterizes the RD.

However, as mentioned in the introduction, this result refers to arbitrary, finite points in time, and does not hold if infinite time is considered. When time tends to infinitely, the asymptotic behavior of the discrete time learning process can be different from the asymptotic behavior of the continuous time RD.

Additionally, the RD treats the player as a population (of strategies). By the construct of the continuous time of Börgers and Sarin, in each iteration, a random sample of the population is taken to play the game. Due to the law of large numbers, this sample represents the whole population. However, in the discrete learning process, at each time, only one strategy is played by each individual. Moreover, the outcome of each of these interactions affects the probabilities with which the strategies are used in the next time step.

These results have been extended in Tuyls et al. (2006). It was shown that the positive reinforcement model by Börgers and Sarin (1997) corresponds to the learning automata. Moreover, a similar dynamics was derived for Boltzmann action selection. The theoretical results were verified with experiments in 3 classes of  $2 \times 2$  games.

These works suggest that other dynamics, e.g., based on less gradual adjustments may lead to different results in other games as well. We also remark that at least one of the games considered in this paper is one in which not only the analytical computation of the RD is non-trivial, but also the fact that more populations and actions are involved contribute to results being less intuitive as the cases in Börgers and Sarin (1997); Tuyls et al. (2006).

Next, for sake of clarity, we briefly mention the Q-learning method, as well as discuss some related work on multiagent reinforcement learning (MARL).

### Individual and Multiagent RL

Reinforcement learning (RL) by a single agent problems can be modeled as Markov decision processes (MDPs). An experience tuple  $\langle s, a, s', r \rangle$  denotes the fact that the agent was in state  $s$ , performed action  $a$  and ended up in  $s'$  with reward  $r$ . Q-learning is a popular model-free algorithm in which the update rule for each experience tuple is given in Equation 1 where  $\alpha$  is the learning rate and  $\gamma$  is the discount for future rewards.

$$Q(s, a) \leftarrow Q(s, a) + \alpha (r + \gamma \max_{a'} Q(s', a') - Q(s, a)) \quad (1)$$

When many individuals or agents learn simultaneously, the problems are well known. They arise mainly due to the fact that while one agent is trying to model the environment (other agents included), the others are doing the same and potentially changing the environment they share.

Besides, in MARL an issue is the exponential increase in the space of joint states and joint actions, if agent  $i$  *explicitly models the states and actions of other agents*. The decision

on whether or not to include joint states and/or joint actions in the learning process of  $i$  is a key one as it has severe implications. In fact, most of the game-theoretic literature concentrates on games with few players and few actions because otherwise it is computationally prohibitive.

This paper deals with a large number of agents, thus approaches such as JAL (joint agent learners, Claus and Boutilier (1998)) cannot be used because an explicit model of other agents' actions, states, and rewards is necessary. After JAL, several approaches have been proposed for related as well as more general MARL problems. However, they cannot be used due to some restrictions: zero-sum game (e.g., Littman (1994)), few agents and/or few actions and/or assumption of perfect monitoring (e.g., Hu and Wellman (1998); Lauer and Riedmiller (2000); Kapetanakis and Kudenko (2002); Kuminov and Tennenholtz (2008)).

## Methods

### Formalization of Population Games

Population games are quite different from the games studied by the classical GT because population-wide interaction generally implies that the payoff to a given member of the population is not necessarily linear in the probabilities with which pure strategies are played. A population game can be defined as follows.

- **(populations)**  $\mathcal{P} = \{1, \dots, p\}$ : society of  $p \geq 1$  populations of individuals where  $|p|$  is the number of populations
- **(strategies)**  $\mathcal{S}^p = \{s_1^p, \dots, s_m^p\}$ : set of strategies available to agents in population  $p$
- **(payoff function)**  $\pi(s_i^p, \mathbf{q}^{-p})$

Agents in each population  $p$  have  $m^p$  possible strategies. Let  $n_i^p$  be the number of individuals using strategy  $s_i^p$ . Then, the fraction of individuals using  $s_i^p$  is  $x_i^p = \frac{n_i^p}{N^p}$ , where  $N^p$  is the size of  $p$ .  $\mathbf{q}^p$  is the  $m^p$ -dimensional vector of the  $x_i^p$ , for  $i = 1, 2, \dots, m^p$ . As usual,  $\mathbf{q}^{-p}$  represents the set of  $\mathbf{q}^p$ 's when excluding the population  $p$ . The set of all  $\mathbf{q}^p$ 's is  $\mathbf{q}$ . Hence, the payoff of an agent of population  $p$  using strategy  $s_i^p$  while the rest of the populations play the profile  $\mathbf{q}^{-p}$  is  $\pi(s_i^p, \mathbf{q}^{-p})$ . Consider a (large) population of agents that can use a set of pure strategies  $\mathcal{S}^p$ . A population profile is a vector  $\sigma$  that gives the probability  $\sigma(s_i^p)$  with which strategy  $s_i^p \in \mathcal{S}^p$  is played in  $p$ .

One important class within population games is the class of symmetric games, in which two random members of a *single* population meet and play the stage game, whose payoff matrix is symmetric. The reasoning behind these games is that members of a population cannot be distinguished, i.e., two meet randomly and each plays one role but these need not to be the same in each context. Thus the symmetry. However, there is no reason to restrict oneself to a symmetric modeling in other scenarios beyond population biology. For

| $x_1$ |  | <b>4/6/5</b> | 0/0/0        |
| $y_1$ |  | 0/0/0        | <b>0/0/0</b> |

Table 2: Payoff matrices for the 3PEOY game; payoffs are for player 1 / player 2 / player 3 (the four Nash equilibria in pure strategies are indicated in boldface).

instance, in economics, a market can be composed of buyers and sellers and these may have asymmetric payoff functions and/or may have sets of actions whose cardinality is not the same. In asymmetric games, each agent belongs to one class determining the set of legal strategies.

Before we present the particular modeling of asymmetric population game, we introduce the concept of RD.

The previously mentioned idea that the composition of the population of individuals (and hence of strategies) in the next generations changes with time suggests that we can see these individuals as replicators. In the RD, the rate of use of a determined strategy is proportional to the payoff difference with the mean expected payoff, as in Eq. 2. As previously defined, the fraction of agents using  $s_i^p$  is  $x_i^p = \frac{n_i^p}{N^p}$ . The state of population  $p$  can be described as a vector  $\mathbf{x}^p = (x_1^p, \dots, x_m^p)$ . We are interested in how the fraction of agents using each strategy changes with time, i.e., the derivative  $\frac{dx_i^p}{dt}$  (henceforth denoted  $\dot{x}_i^p$ ).

$$\dot{x}_i^p = (\pi(s_i^p, \mathbf{x}^p) - \bar{\pi}(\mathbf{x}^p)) \times x_i^p \quad (2)$$

In Eq. 2,  $\bar{\pi}(\mathbf{x}^p)$  is the average payoff obtained by  $p$ :

$$\bar{\pi}(\mathbf{x}^p) = \sum_{i=1}^m x_i^p \pi(s_i^p, \mathbf{x}^p)$$

Obviously, to analytically compute this average payoff, each individuals would have to know all the payoffs, which is quite unrealistic.

## Two Scenarios for Three Player Games

In the three-population games considered here, to avoid confusion we use the term "player" with its classical interpretation, i.e., the decision-makers of the normal form game (NFG). Because this game is played by randomly matched individuals, one from each population, we call these individuals "agents". Thus player refers to a population of agents.

The just given description of the general population game is instantiated for our particular scenarios as follows.

**Three Player Matching Pennies** From the general definition of a population game given in the previous section, this is the particular instance for the three player matching pennies (henceforth 3PMP):

- **(populations)**  $\mathcal{P} = \{1, 2, 3\}$
- **(strategies)** for each population  $p \in \mathcal{P}$ :  $\mathcal{S}^1 = \mathcal{S}^2 = \mathcal{S}^3 = \{H, T\}$
- **(payoff function)** see Table 1

From the payoff matrix for this game (Table 1), one sees that as in the two player original game, there is a single Nash equilibrium, in mixed strategies. This is indicated in Table 3. In this table, columns 2–3 specify  $\mathbf{x}^1$  (fraction of agents selecting each strategy H and T in population  $p = 1$ ), columns 4–5 specify  $\mathbf{x}^2$  of  $p = 2$ , and columns 6–7 specify  $\mathbf{x}^3$  of  $p = 3$ . The last column gives the payoffs for the agents.

**Three Player Coordination Game** The second three player game that we consider is a kind of coordination game. As mentioned, it pays a non-zero quantity to the players when exactly one of them select one of the two strategies. Henceforth we denominate this game by 3PEOY (three players, where exactly one should select strategy  $y$ ). This game has eight Nash equilibria, four of which are in pure strategies, thus making the task of coordinating over equilibrium selection very hard for the agents.

The corresponding population game is then defined:

- **(populations)**  $\mathcal{P} = \{1, 2, 3\}$
- **(strategies)** for each population  $p \in \mathcal{P}$ :  $\mathcal{S}^1 = \{x_1, y_1\}$ ,  $\mathcal{S}^2 = \{x_2, y_2\}$ , and  $\mathcal{S}^3 = \{x_3, y_3\}$ .
- **(payoff function)** see Table 2

| profile  | $x_H^1$       | $x_T^1 = (1 - x_H^1)$ | $x_H^2$       | $x_T^2 = (1 - x_H^2)$ | $x_H^3$       | $x_T^3 = (1 - x_H^3)$ | payoff |

| $\sigma_c$ | 0              | 1                     | 1              | 0                     | 1              | 0                     | 5/4/6                                        |
| $\sigma_d$ | 1              | 0                     | 0              | 1                     | 1              | 0                     | 6/5/4                                        |
| $\sigma_e$ | 1              | 0                     | $\approx 0.44$ | $\approx 0.56$        | $\approx 0.54$ | $\approx 0.45$        | $\approx 2.63 / \approx 2.73 / \approx 2.22$ |
| $\sigma_f$ | $\approx 0.44$ | $\approx 0.56$        | $\approx 0.54$ | $\approx 0.45$        | 1              | 0                     | $\approx 2.73 / \approx 2.22 / \approx 2.63$ |
| $\sigma_g$ | $\approx 0.54$ | $\approx 0.45$        | 1              | 0                     | $\approx 0.44$ | $\approx 0.56$        | $\approx 2.22 / \approx 2.63 / \approx 2.73$ |
| $\sigma_h$ | $\frac{2}{3}$  | $\frac{1}{3}$         | $\frac{2}{3}$  | $\frac{1}{3}$         | $\frac{2}{3}$  | $\frac{1}{3}$         | $\approx 2.22 / \approx 2.22 / \approx 2.22$ |

Table 4: Eight Nash equilibria for the 3PEOY game.

The eight Nash equilibria appear in Table 4. In this table, columns 2–3 specify  $\mathbf{x}^1$  (fraction of agents selecting each strategy  $s_i^1$  in population  $p = 1$ ), columns 4–5 specify  $\mathbf{x}^2$  of  $p = 2$ , and columns 6–7 specify  $\mathbf{x}^3$  of  $p = 3$ . The last column gives the payoffs for the agents. For example, for the first equilibrium (profile  $\sigma_a$ ), because  $x_x^1 = 1$ ,  $x_x^2 = 1$ , and  $x_x^3 = 0$ , all agents in  $p = 1$  select action  $x_1$ , all agents in  $p = 2$  select  $x_2$  and all agents in  $p = 3$  select  $y_3$ .

Regarding the mixed strategy profile  $\sigma_e$  (for example), all agents in  $p = 1$  select action  $x_1$  (because  $x_y^1 = 0$ ), whereas in the other two populations nearly half of the agents select each action. Profiles  $\sigma_f$  to  $\sigma_h$  can be similarly interpreted.

In the classical GT interpretation of equilibrium, profiles  $\sigma_a$ ,  $\sigma_b$ ,  $\sigma_c$ , and  $\sigma_d$  would be Nash equilibria in pure strategies, while the other four equilibria would mean that agents randomize between at least two pure strategies. The EGT interpretation thought is as follows. If we consider that we are dealing with three populations of agents, we can think about the equilibria in terms of the percentage of individuals in one of the three populations that in fact select one of the actions available. This seems a more reasonable explanation for the concept of mixed strategies, given that, at each time, agents in fact only select an action.

The same reasoning obviously applies to the 3PMP game which has only a mixed strategy profile.

Moreover, it must also be noticed that in asymmetric games, all ESS are pure strategies (for a proof see, e.g., Webb (2007)). Thus, for the 3PEOY game, only  $\sigma_a$  to  $\sigma_d$  are candidates for ESS.

Note from Table 4 that in this game  $\sigma_b$ , though a Nash equilibrium, is not efficient (all agents receive zero), thus the learning models tested here should be able to recognize this.

### Replicator Dynamics, Evolutionary Approach and Reinforcement Learning

As mentioned in the introduction, the continuous RD model, which is hard to justify, can be reproduced with some forms of learning. To compare the performance of these learning models, we have first formulated the continuous RD for our specific three-population game. The equations can be derived from Eq. 2.

In both the 3PMP and 3PEOY, we have checked which Nash equilibria are stable. In the 3PEOY in particular, the Nash equilibria that need to be investigated are, as mentioned, those in pure strategies, i.e.,  $\sigma_a$  to  $\sigma_d$  from Table 4. To check which are the ESSs, it is necessary to analyze which are the stable rest points. In simple games, e.g.,  $2 \times 2$  or even symmetric  $2 \times 3$  this can be done graphically. However, because our problem involves several variables the divergence operator was used.

Now we turn to the approaches based on evolution and reinforcement learning. In both cases, in each time step, agents from each population  $p$  play  $g$  games whose payoffs are given in Table 1 and Table 2.

For the evolutionary approach, mutations create genetically mutated versions of the agents. Here we use a mutation rate  $p_m$ : at each time step, each agent in the population receives a new strategy with probability  $p_m$ . We recall that, according to Börgers and Sarin (1997), it is expected that if the adjustment is not gradual, there may be no convergence to the behavior of the continuous RD. The sum of the payoffs obtained by playing these  $g$  games is then the fitness of the agent. After these  $g$  games are played, the populations of agents are reproduced: In each population  $p$ , the fittest agents have a higher probability of being selected. Then each individual suffers mutation with probability  $p_m$ , which means that its strategy is changed to another one randomly selected.

For the reinforcement learning, agents learn using individual Q-learning (Eq. 1), thus assessing the value of each strategy by means of Q values. For action selection,  $\epsilon$ -greedy was used, i.e., action selection is random with probability  $\epsilon$ , otherwise it is greedy. In line with the just mentioned issue of gradual adjustments, and from Tuyls et al. (2006), we know that the value of  $\epsilon$  is key to reproduce the behavior of the continuous RD.

## Experiments and Results

In this section we discuss the numerical simulations of the evolutionary and learning based approaches and compare them with the continuous RD, from which we know the Nash equilibria, and the candidates to be ESSs, for both games 3PMP and 3PEOY.

We are interested in investigating issues such as what happens if each population  $p$  starts using a given profile  $\sigma^p$  in games that have more than one equilibrium. To which extent the rate  $p_m$  shifts this pattern? For instance, if the population starts using any  $\sigma^p$ , what happens if it is close to (but not actually at)  $\sigma^*$ ? Will it tend to evolve towards  $\sigma^*$  or move away? If it reaches  $\sigma^*$ , how long has it taken? What happens if there are multiple equilibria?

The main parameters, as well as the values that were used in the simulations are:  $\mathcal{P} = \{0, 1, 2\}$ ,  $N^0 = N^1 = N^2 = 300$ ,  $g = 10,000$ ,  $\alpha = 0.5$ ;  $\epsilon$ ,  $\Delta$  (number of time steps) and  $p_m$  were varied. In all cases, at step 0, agents select strategies from a uniform distribution of probability.

The next subsections discuss the evolutionary and the reinforcement learning approaches respectively.

### Adaptation with Evolutionary Approach

In this case, because more than two variables (strategies) are involved, it is not possible to show typical (2d) RD-like plots that depict the trajectory of these variables. Therefore, as an alternative to show the dynamics, we use heatmaps.

We start with the 3PMP game. In the plots that appear in Figure 1 (which were reduced due to lack of space), heatmaps are used to convey the idea of the intensity of the selection of each of the 8 joint actions (represented in the vertical axis) along time (horizontal axis), with  $\Delta = 1000$  time steps. These 8 joint actions are those that appear in Table 1. Due to an internal coding used, the 8 joint actions are labeled such that 0 and 1 mean the selection of first strategy ( $H$ ) and second strategy ( $T$ ) respectively.

In each triplet (joint action), the first digit indicates the action of  $p = 3$ , the second digit is for the action of  $p = 2$ , and the third digit is for  $p = 1$ .

In the heatmaps, to render the figure cleaner we just use shades of gray color (instead of hot colors as usual). In any case, the darker the shade, the more intense one joint action is selected. Thus we should expect that the Nash equilibria correspond to the darker strips.

Figure 1: 3PMP: Evolution of Dynamics for Different values of  $p_m$ , evolutionary approach.

In Figure 1 it is possible to see that there is no convergence to any of the pure strategy. Rather, agents cycle among 6 of the joint actions. This happens for all value of  $p_m$  tested. The two joint actions that pay  $-1$  to all agents are quickly discarded. Remember that a different pattern occurs when fictitious play was used, according to Börgers and Sarin (1997).

Regarding the second game, 3PEOY, plots appear in Figure 2. Again, there are 8 joint actions. These are labeled such that 0 and 1 mean the selection of first strategy ( $x$ ) and second strategy ( $y$ ) respectively.

In particular, the four Nash equilibria ( $\sigma_a$ ,  $\sigma_b$ ,  $\sigma_c$ , and  $\sigma_d$ ) in pure strategies of these game are represented as: 100, 111, 001 and 010 respectively.

Figure 2: 3PEOY: Evolution of Dynamics for Different values of  $p_m$ , evolutionary approach.

In Figure 2 we show how the selection evolves along time, for two values of  $p_m$ . Figure 2(a) is for  $p_m = 10^{-1}$ , i.e., changes in strategy occur with this rate. In these particular plot we show clear convergence to  $\sigma_a$  (100). However, convergence is also possible to other joint actions, as, e.g. 010 and 001, but not to 111 because this is a non efficient Nash equilibria. We do not show all plots as they are similar to Figure 2(a).

When  $p_m$  is lowered as in Figure 2(b), the pattern is the same, i.e., clear convergence to either  $\sigma_a$ ,  $\sigma_c$  or  $\sigma_d$ .

When  $p_m$  is set higher, this pattern does not occur, i.e., there is no clear convergence to any of the Nash equilibria. An extreme case with  $p_m = 0.5$  is depicted in Figure 2(c), where one sees that the performance is poor due to the high rate of changes by the agents. Interestingly, frequently, the Pareto inefficient Nash equilibria  $\sigma_b$  is selected, which means payoff of zero to each agent.

### Reinforcement Learning

We now turn to the individual learning using Q-learning. Experiments were run with different values of  $\alpha$  and change in  $\varepsilon$ . It seems that  $\alpha$  has much less influence in the result than  $\varepsilon$ . Thus we concentrate on  $\alpha = 0.5$ .

For both games, here we show plots for  $\varepsilon$  starting at 1.0 with various decay rates each time step.

For the 3PMP game, to render the picture more clear, plots in Figure 3 depict the evolution within time of the percentage of H being selected by agents in population  $p = 1$  only as others are similar. One can see that agents shift from H to T and vice-versa. This happens no matter if the decay of  $\varepsilon$  is fast (Figure 3(a)) or more slow (Figure 3(b)).

For the 3PEOY game, due to a more clear convergence pattern, it is possible to plot not only the percentage of selection of action  $x$  by agents in the first population, but also for  $p = 2$  and  $p = 3$ . Figure 4 depicts them. Figure 4(a) refers to a faster decay of  $\varepsilon$ , 0.9 at each time step, and shows convergence to  $\sigma_c$ . However we note that similar patterns occur leading to  $\sigma_a$  and  $\sigma_d$  (but not  $\sigma_b$ ). Figure 4(b) is for decay of 0.99. In this particular plot, convergence is to  $\sigma_d$ .

How agents have converged to a given profile is better seen examining the trajectories of the probabilities to play each strategy, for each population. Due to the number of variables, it is not possible to plot them all together. Thus we opted to show the behavior of selected variables in a pairwise fashion, namely  $x_1 \times x_2$ ,  $x_1 \times x_3$ ,  $x_2 \times x_3$  (Figure 5). In this plot, for each of the three pairs, the  $x$ -axis represents the probability with which the first component of the pair selects strategy  $x$ , while the  $y$ -axis represents the probability with which the second component of the pair selects  $x$ .

It is possible to see that although these percentages all start at 0.5, they all converge to 1.0 or close. In the particular plot convergence was to  $x_1 = 1$ ,  $x_2 = 0$ , and  $x_3 = 1$  and hence this corresponds to the same pattern as in Figure 4(b),  $\sigma_d$ .

Figure 5: Trajectories:  $x_1 \times x_2$ ,  $x_1 \times x_3$ , and  $x_2 \times x_3$  (all start at  $x_i = 0.5$ ).

In short, some conclusions can be drawn from these simulations. First, simultaneous learning by the agents does not always lead to the Nash equilibrium, much less to the ESS computed for the corresponding RD of the static NFG.

If an evolutionary approach is used, depending on the  $p_m$  rate, any of the Nash equilibria may establish, or agents may be stuck at a sub-optimal state.

This is in line with the result in Börgers and Sarin (1997), which prescribes gradual adjustments. Profiles that are dominated do not establish.

### Conclusion

In this paper, two three-population games were used to illustrate the patterns of convergence when different methods are used for replicating the dynamics prescribed by analytical, continuous methods such as the RD. It was seen that the extent of match between the continuous RD and discrete learning methods (whether an evolutionary approach or Q-learning) depends on the pace of the adjustment.

Also, compared to results in Tuyls et al. (2006), an extra population in the matching pennies game has slowed down the convergence as it takes more time for agents to learn in the presence of three populations.

Future work will consider information broadcast to agents, in order to have a further way to model action selection and try to improve the coordination task, as well as investigate issues regarding correlated equilibria.

## Abstract

Grammatical Evolution is an evolutionary algorithm that can evolve complete programs using a Backus Naur form grammar as a plug-in component to describe the output language. An important issue of Grammatical Evolution, and evolutionary computation in general, is the difficulty in dealing with deceptive problems and avoid premature convergence to local optima. Novelty search is a recent technique, which does not use the standard fitness function of evolutionary algorithms but follows the gradient of behavioral diversity. It has been successfully used for solving deceptive problems mainly in neuro-evolutionary robotics where it was originated. This work presents the first application of Novelty Search in Grammatical Evolution (as the search component of the later) and benchmarks this novel approach in a well-known deceptive problem, the Santa Fe Trail. For the experiments, two grammars are used: one that defines a search space semantically equivalent to the original Santa Fe Trail problem as defined by Koza and a second one which were widely used in the Grammatical Evolution literature, but which defines a biased search space. The application of novelty search requires to characterize behavior, using behavior descriptors and compare descriptions using behavior similarity metrics. The conducted experiments compare the performance of standard Grammatical Evolution and its Novelty Search variation using four intuitive behavior descriptors. The experimental results demonstrate that Grammatical Evolution with Novelty Search outperforms the traditional fitness based Grammatical Evolution algorithm in the Santa Fe Trail problem demonstrating a higher success rates and better solutions in terms of the required steps.

## Background

### Grammatical Evolution

Grammatical Evolution (O'Neill and Ryan, 2001) is an evolutionary algorithm that can evolve complete programs in an arbitrary language using populations of variable-length binary strings. Namely, a chosen evolutionary algorithm (typically a variable-length genetic algorithm) creates and evolves a population of individuals and the binary string (genome) of each individual determines which production rules in a Backus Naur Form (BNF) grammar definition are used in a genotype-to-phenotype mapping process to generate a program. In natural biology, there is no direct mapping

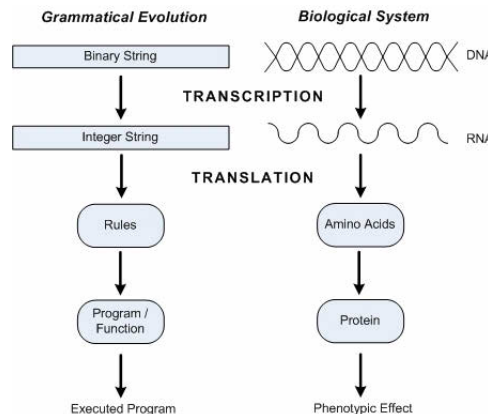

Figure 1: Comparison between the GE system and a biological genetic system. Cited in (O'Neill and Ryan, 2001), p.351.

between the genetic code and its physical expression. Instead, genes guide the creation of proteins, which affect the physical traits either independently or in conjunction with other proteins (Ryan et al., 1998). Grammatical Evolution treats each genotype to phenotype transition as a "protein" which cannot generate a physical trait on its own. Instead, each one protein can result in a different physical trait depending on its position in the genotype and consequently, the previous proteins that have been generated.

Fig. 1 shows the comparison between the GE system and a biological genetic system (O'Neill and Ryan, 2001). The binary string of the genotype of an individual in GE is equivalent to the double helix of DNA of a living organism, each guiding the formation of the phenotype. In the case of GE, this occurs via the application of production rules to generate the terminals of the resulted program (phenotype) and in the biological case, directing the formation of the phenotypic protein by determining the order and type of protein subcomponents (amino acids) that are joined together.

Before the evaluation of each individual, the following steps take place in Grammatical Evolution:

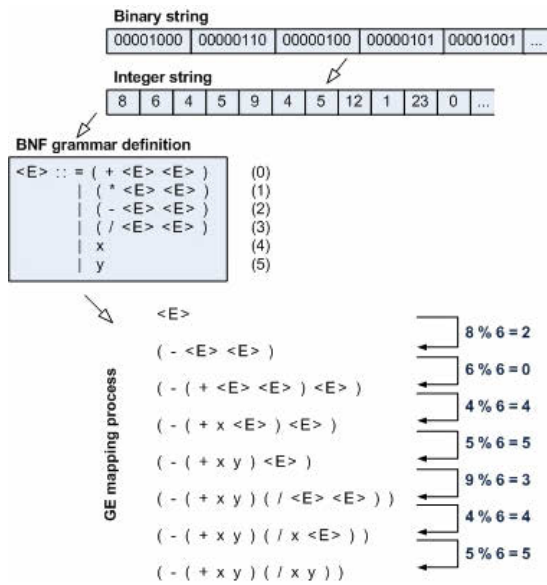

Figure 2: GE mapping process. From Dempsey et al. (2006), p. 2588, (with minor changes)

- i The genotype (a variable-length binary string) is used to map the start symbol of the BNF grammar definition into terminals. The grammar is used to specify the legal phenotypes.
- ii The GE algorithm reads "codons" of typically 8 bits (integer codons are also widely adopted) and the integer corresponding to the codon bit sequence is used to determine which form of a rule is chosen each time a non-terminal to be translated has alternative forms. If while reading "codons", the algorithm reaches the end of the genotype, it starts reading again from the beginning of the genotype (wrapping).
- iii The form of the production rule is calculated using the formula  $form = codon \bmod forms$  where *codon* is the codon integer value, and *forms* is the number of alternative forms for the current non-terminal.

An example of the mapping process employed by Grammatical Evolution is shown in Fig. 2. In this example, the first codon of the genotype of the individual is the binary string 00001000 which is the binary form of the integer 8. The start symbol  $\langle E \rangle$  has six alternative forms, therefore the form to be applied is this with label 2 ( $8 \% 6$ ) which results in the expression  $( - \langle E \rangle \langle E \rangle )$ . The next codon is then read in order to replace the first non-terminal symbol  $\langle E \rangle$  of the new expression, and this goes on until the expression contains only the terminal symbols  $x$  and  $y$  and any of the arithmetic operators. Namely, until all of the non-terminal symbols have been replaced.

Figure 3: "The Santa Fe Trail.

After the mapping process (i.e. the creation of the phenotype), the fitness score is calculated and assigned to each individual (phenotype) according to the given problem specification. These fitness scores are sent back to the evolutionary algorithm which uses them to evolve a new population of individuals. Grammatical Evolution is a flexible and promising grammar-based evolutionary algorithm with two unique features inspired from molecular biology: genetic code degeneracy which improves genetic diversity, due to its many-to-one genotype-to-phenotype mapping mechanism; and genetic material reuse, due to the genome wrapping it applies. Even though Grammatical Evolution shows competence on a series of problems where it has been applied, the experiments conducted by Georgiou and Teahan (2010, 2011) and Georgiou (2012) cast doubt about its effectiveness and efficiency on deceptive problems such as Artificial Ant and Maze searching.

### The Santa Fe Trail Problem

The Santa Fe Trail is the most common instance of the Artificial Ant problem and was designed by Christopher Langton (Koza, 1991). It is a standard and challenging problem, which is widely used for benchmarking in Genetic Programming (Koza, 1991, 1992) and Grammatical Evolution (O'Neill and Ryan, 2001, 2003).

This problem can be briefly described as finding a computer program to control an artificial ant, within a limited amount of steps, such that it can find all food items forming a twisting trail in a 32 x 32 toroidal plane grid. The trail is composed by 89 food pellets distributed non-uniformly along it, and has 55 gaps and 21 turns (see Fig. 3). The Santa Fe Trail has the following irregularities: single gaps, double gaps, single gaps at corners, double gaps at corners (short knight moves) and triple gaps at corners (long knight moves) (Koza, 1991).

The artificial ant starts in the upper left cell of the grid (0,0), facing east, and can perform three primitive actions: *move*, *turn right* and *turn left* - each action consumes one step. The *move* action moves the ant forward one square in the direction it is currently facing. When the ant moves into a square, it eats the food if there is any. The other two actions

turn the ant right or left respectively by 90 degrees, without moving the ant. The ant can use a binary sensing boolean operator *food ahead*, which comes with no cost in moves. This sensing operator looks into the square the ant is currently facing and executes one of its arguments depending upon whether the square ahead contains food or is empty. Besides the sensing operator, Koza (1991) introduced the unlimited sequence operator *progn* that executes its arguments in order. Alternatively, Koza (1992) introduced two and limited sequence *progn2* and *progn3*, taking two and three arguments respectively. This difference regarding the sequence operators used introduces a representational bias, but does not affect the ant control possibilities, since any *progn* subtree can be translated into semantically equivalent subtrees using *progn2* and *progn3* operators and vice versa (Robilliard et al., 2005).

During the evaluation of the ant, its program is iterated until exhausting the steps limit or eating all food items. There is no unanimity in the literature regarding the fixation of the maximal number of steps an ant is allowed to perform. Robilliard et al. (2005) note that Koza said he arbitrarily fixed to 400, but Langdon and Poli (1998) set the limit to 600 steps, assuming a possible mistype in Koza's paper. O'Neill and Ryan (2003) set the maximum number of steps to 615 and Georgiou (2012) benchmarks a variety of GE configurations using 650 steps.

As the goal is to collect the maximal number of food items laid down in the trail, the customary fitness function is the amount of food collected by the ant, or in the case of minimization, the number of pellets missed out of the total 89 on the trail.

This benchmark problem is still repeatedly used (Georgiou and Teahan, 2010; Lehman and Stanley, 2010; Doucette and Heywood, 2010) because of its interesting characteristics: it has a large search space, full of global and local optima and many plateaus riven with deep valleys, which may be indicative of real problem spaces (Langdon and Poli, 1998). More, there are low and middle order schemas which are required as stepping stones to build solutions but which are below average fitness. Langdon and Poli (1998) have shown that GP does not perform significantly better than random search on this problem since it contains multiple levels of deception, where solutions have low fitness neighbors. The search space is highly deceptive because it has many high scoring non-optimal programs that do not correspond to trail following behavior: random policies may collect many food items.

### Performance of GE on the Santa Fe Trail Problem

O'Neill and Ryan (2003) compared Grammatical Evolution with Genetic Programming, using the Santa Fe Trail problem as a benchmark, fixing the steps upper limit to 615. They have used the grammar in Fig. 4 (from now on called BNF-O'Neill grammar) and the experiments results were fa-

```
<code> ::= <line> | <code> <line>
<line> ::= <condition> | <op>
<condition> ::= ifelse food-ahead
               [ <line> ] [ <line> ]
<op> ::= turn-left | turn-right | move
```

Figure 4: "BNF-O'Neill grammar definition.

```
<expr> ::= <line> | <expr> <line>
<line> ::= ifelse food-ahead
               [ <expr> ] [ <expr> ] | <op>
<op> ::= turn-left | turn-right | move
```

Figure 5: "BNF-Koza grammar definition.

vorable to GE.

The comparison SFT experiments were later questioned by Robilliard et al. (2005). They have found that the search space of programs possible by BNF-O'Neill grammar was not semantically equivalent to the set of programs possible within the original SFT definition. The former is narrower: any original SFT program can be translated into a semantically equivalent BNF-O'Neill program but the converse is not true. Robilliard et al. (2005) argue that they found no solution in the Santa Fe Trail problem using Grammatical Evolution, up to and including 600 time steps in their experiments, and they note that almost all Grammatical Evolution publications mention an upper limit of 615 time steps. Only in O'Neill and Ryan (2001) with Grammatical Evolution is the limit reported as 600 steps, which Robilliard et al. (2005) claim is a mistype.

Georgiou and Teahan (2010) have made a series of experiments where GE gives very poor results in the Santa Fe Trail problem with a search space semantically equivalent to the search space used in the original problem (Koza, 1991). They have used the SFT-BAP grammar cited in Robilliard et al. (2005), from now on named BNF-Koza (see Fig. 5), which defines a search space of programs semantically equivalent to the Koza's original (Robilliard et al., 2005). Indeed, the same work proved experimentally that GE literature (O'Neill and Ryan, 2001, 2003) uses a BNF grammar which narrows the original search space and consequently gives an unfair advantage to GE when it is compared against GP in the SFT problem. As noted by Robilliard et al. (2005) the BNF-O'Neill grammar does not allow multiple <op> statements or sequences of <op> and <condition> statements in the branches of the <condition> production rule, in contrast with the first production rule of <line> in the BNF-Koza.

In the experiments of Georgiou and Teahan (2010) the maximum allowable steps for the ant was set to 650. The reason for this increase was to give Grammatical Evolution the chance to find more solutions using the investigated BNF grammars in order that the sample of the solutions found

and the comparison of the effects of these grammars on the performance of Grammatical Evolution being more encompassing. Furthermore, they have proved experimentally that during an evolutionary run GE is not capable of finding solutions using the BNF-O'Neill grammar definition with less than 607 steps. BNF-O'Neill defines a smaller search space, biasing the search towards areas where a solution may be found more easily (higher success rate) but with the cost of excluding areas where more efficient programs (using less steps) exist. Note that the easy incorporation of domain knowledge, by changing the grammar, and biasing the search, is a great advantage of the grammar representation used by GE. But we should be careful not to exclude good solutions (the ones which require less steps), as it is the case of BNF-O'Neill.

The best solution we know so far for the SFT problem, in GP or GE, requires only 337 steps, and it was generated by CGE (Georgiou and Teahan, 2011), one of the GE variations developed over the last years.

### Promoting diversity in GP to overcome deception

Diversity promotion and maintenance, relying generally on the genotype and fitness function, has been the main approach to mitigate deception and stagnation in GP. A variety of different techniques have been proposed in order to preserve genotypic diversity, that make use of different measures to compare genotypes. We are going to refer only some of them: higher mutation rates (Banzhaf et al., 1996), larger population sizes (Ciesielski and Mawhinney, 2002), fitness shaping (Luke, 1998), aiding explicit objectives to promote genotypic diversity, together with a goal-oriented one, in a multi-objective scheme (de Jong et al., 2001), replacing the most similar programs (Ciesielski and Mawhinney, 2002), maintaining a diversity of genetic lineages (Burke et al., 2003) and fitness sharing (Ekárt and Németh, 2002). Burke et al. (2002) have shown that genotype diversity approaches manifest a low correlation with fitness.

A different approach is the promotion of phenotypic diversity based on fitness: the use of a selection method which is uniform over the fitness values (Legg and Hutter, 2005) or the phenotype diversity measurement in terms of the number of unique fitness values in the population, using entropy (Rosca, 1995). Burke et al. (2002) concluded that "successful evolution occurs when population converges to similar structure and high fitness diversity" and "the fitness based measures of phenotypes and entropy appear to correlate better with run performance." The phenotype techniques spread individuals across different fitness levels but are not able to maintain diversity in the same fitness levels (Legg and Hutter, 2005). Yan and Clack (2009) pointed out the importance of preserving phenotypic behavioral diversity, in achieving higher fitness and adaptability to dynamic domains, where behavior is not reduced to fitness, being much more detailed.

### Novelty Search

All diversity preserving techniques, described above, take objective-based fitness into account. The Novelty Search (NS) approach, introduced by Lehman and Stanley (2008) is much more radical, as it ignores completely the fitness objective, relying only on behavior diversity as the sole criteria for selection in artificial evolution. Objective based fitness is replaced by novelty and the idea is not to select the most fitted individuals for reproduction but those with the most novel behaviors instead. Novel individuals are rewarded and will guide the search towards finding other novel individuals. NS is driven towards behavior space exploration, looking for what is divergent from the past and present behaviors, regardless of their fitness. The idea is that by exploring the behavior space without any goal besides novelty, ultimately an individual with the desired behavior will be found. Surprisingly, NS has been successful in several deceptive problems (Lehman and Stanley, 2011; Gomes et al., 2012), as it is not dependent of any fixed goal, avoiding the convergence towards local optima.

NS requires the definition of distances between behavior descriptors. Those descriptors may be specific to a task or suited for a class of tasks (Doncieux and Mouret, 2010). The descriptors are normally vectors that capture behavior information along the whole evaluation or which is just sampled at some particular instants. The used descriptors may even change along an evolutionary run. Several general distance functions between behavioral vectors have been suggested: euclidian distance, edit distance, hamming distance, relative entropy and normalized compression distance, fourier analysis, for instance (Doncieux and Mouret, 2010).

Given a behavior function and a distance metric, the novelty score of an individual is computed as the average distance from its  $k$ -nearest neighbors ( $\mu_i$ ) in both the population and the archive (see Eq. 1).

$$\rho(x) = \frac{1}{k} \times \sum_{i=0}^k \text{dist}(x, \mu_i) \quad (1)$$

A point in a sparse area will be highly rewarded and a point in a dense area will receive a low novelty score. There have been several proposed ways of registering the past behaviors but we won't deal with them here, as in our NS application we won't use any archive of past behaviors.

### Novelty Search applied to GP

Lehman and Stanley (2010) were the first to apply novelty search to Genetic Programming. They made experiments in three deceptive tasks: maze navigation, and the two artificial ant benchmarks: the Santa Fe Trail and Los Altos. There is no reference to the features of the best individual evolved, in terms of the number of steps, genotype or phenotype length, but in the end, NS was able to avoid bloat, evolving smaller

programs and outperforming objective based fitness in terms of the number of successfully evolutionary runs.

Doucette and Heywood (2010) used SFT to study the effects of NS on performance and also on solution generalization. NS evolved programs, which eat less food items on average than the traditional fitness based method but they achieved better performance in terms of generalization to new trails.

Naredo et al. (2013) applied NS to evolve GP classifiers and obtained encouraging results when compared to canonical GP. NS exhibited the best results when confronted with difficult problems, but for simple problems, however, the explorative capacity of NS seemed to be a detriment to the search.

### Santa Fe Trail Experiments

All experiments mentioned in this study have been performed using the jGE library (Georgiou and Teahan, 2006), which is a Java implementation of the Grammatical Evolution algorithm, and jGE Netlogo extension (Georgiou and Teahan, 2010), which is a Netlogo extension of the jGE library. We have used the customary fitness function: the number of food items eaten. An invalid individual has a fitness of 0.

In order to evaluate the performance of Novelty Search in the Santa Fe Trail benchmark, we have used both grammars, BNF-ONeill and BNF-Koza. The latter is used because it is semantically equivalent to the original formulation of SFT, and we have used BNF-ONeill also because it has been extensively used in GE literature, although it narrows the original search space excluding good solutions. In order to sample a larger number of solutions we have fixed the maximum allowable steps for the ant to 650, as in (Georgiou and Teahan, 2010).

Note that when Grammatical Evolution is being performed with Novelty Search (NS-GE) every individual must be evaluated to know its fitness score. But that score is not being used for individual selection. The fitness score is only used to evaluate NS-GE performance.

We did not add any archive, thus novelty was only tested against the other individuals in the current population. Our preliminary experiments showed that the addition of an archive of past behaviors did not improve the performance of NS without memory. Moreover, the archive would introduce a memory mechanism that does not exist in the standard GE. In order to track novelty GE requires a small change: the fitness function is replaced by the novelty metric.

### Behavior descriptors

We have evaluated NS using several behavior descriptors, and all of them were compared against the standard GE for both grammars. There is no natural behavior descriptor: we have many possibilities and we wanted to make empirical

comparisons between several of them. The behavior descriptors should ideally be compact in order to capture relevant behavior variation and condense the irrelevant ones. We have to be careful not to conflate the stepping-stones that will lead the evolution towards finding successful solutions. We are going to present our four behavior descriptors (two of them are different samplings of the same behavior characteristic):

**Amount of food eaten** This is the behavior descriptor used by Lehman and Stanley (2010): the amount of food eaten is sampled  $N$  evenly spaced times during an individual evaluation. We have considered two values for  $N$ , in order to cover descriptors with different granularity and implying behavior spaces with different sizes:  $N=1$  and  $N=26$ . In the former case, the amount of food is sampled only once: at the end of the 650 steps or when the food trail is depleted. A sample of 1 means a behavior space of size 90 and a lot of conflation: many different forms of eating the same amount of food will be considered identical. A sampling of 26 means that the amount of food will be registered every 25 steps. The search space of behaviors will be much larger but there are constraints: it will be impossible to eat more than 25 items in each period. An invalid individual or a valid individual that does not eat any food after 650 steps will have a vector filled with 26 zeros or 1 zero depending on the sampling size. We have used the Euclidean distance for measuring similarity between behaviors.

**Food eaten sequence** This is a behavior descriptor similar to the one used by Doucette and Heywood (2010) in his SFT experiments. The behavior descriptor is a vector of size  $89 \times 2$ , containing the food item coordinates in the order in which they were eaten. The  $x$  and  $y$  coordinates of the first food item eaten occupy the first and second vector position, respectively. The 3rd and 4th vector positions are occupied respectively by the  $x$  and  $y$  coordinates of the second food item eaten. If the ant ate  $N$  food items, being  $N$  less than 89, the first  $N \times 2$  vector cells will be occupied by the  $N$  food item position coordinates and all the other vector cells will be filled by the  $x$  and  $y$  coordinates of the  $N$ th food item position. We have to describe the behavior of ants that do not eat any food item and also the invalid individuals. Both will have a vector filled with 0s. Note that not all of the food position combinations are possible because there are natural constraints imposed on the space of behaviors by the number of maximal steps. For example, it will be impossible to have the food items in reverse order: going to the end of the trail and then following it upside down. We will use the Euclidean distance for measuring similarity between behaviors.

**Steps sequence** We have a vector of 89 cells where the  $n$ th cell will be filled by the number of steps necessary to eat the  $n$ th food item. In case the ant has eaten only  $N$  ( $<89$ ) food items, every cell after the  $N$ th will be filled by the dummy

value. For example, this vector  $[1, 2, 3, *, *, *]$  means that one food item was eaten after the first move, a second food item after the second move, a third food item after three steps and then no more food items were eaten. An invalid individual will have a vector filled with the value \*. Note that again the behavior descriptor imposes constraints on the space of possible behaviors. The vector is always sorted in increasing order, except the dummy \*. We have used a variation on the Euclidean distance (see Eq. 2) for measuring the distance between behavior vectors using this descriptor. The subtraction in the Euclidean formula is substituted by a function  $dif(v, w)$  in order to deal with the dummy value \* (absence of food). Consider two vectors  $v$  and  $w$ , each one with 89 cells:  $v = (v_1, v_2, \dots, v_{89})$  and  $w = (w_1, w_2, \dots, w_{89})$ .

$$dist(v, w) = \sqrt{\sum_{i=0}^{89} dif(v_i, w_i)^2} \quad (2)$$

We want to penalize, as being different, the behavior vectors that have less food items (more \*s). This way the difference between a dummy value and any number of steps is 500. The difference function between the values from two corresponding cells is given by Eq. 3.

$$dif(x, y) = \begin{cases} 0 & \text{if } x=* \text{ and } y=* \\ x - y & \text{if } x \neq * \text{ and } y \neq * \\ 500 & \text{otherwise} \end{cases} \quad (3)$$

## Experiments setup

Five distinct experiments were performed to evaluate the standard GE and NS-GE with the four different descriptors using the BNF-Koza grammar and another five for BNF-ONeill. Each experiment consisted on 100 evolutionary runs. For each method, we have measured performance in terms of the success or hit rate (number of runs evolving individuals that eat all 89 food items) and the average quality of hits, (average number of steps necessary to eat all the 89 items). We also have measured the average number of food items eaten, the average number of generations for a hit, and finally the minimal number of steps of a hit. The tableau in Table 1 shows the settings and parameters of the experiments.

After some exploration, for almost all behavior descriptors we have chosen 10 for the parameter  $K$ , i.e. the number of nearest neighbors checked in NS (see Eq. 1). The only exception was the steps sequence descriptor: the best value for  $K$  was 5. We have used 50 as the maximum number of generations and a population of 500 individuals, which are widely used values in GP for the SFT. A Generation Gap of 90% means that in a population of 500 individuals the 50 best individuals will survive in the next generation and the worst 450 are replaced. Also, the standard genetic operators of mutation (point) and crossover (one-point) have been used.

|                        |                                                                                                                                                                                                                                                  |

Table 1: Summarizing Tableau for the SFT Problem.

## Results

The experimental results for BNF-Koza and BNF-O'Neill can be seen in Table 2 and Table 3, respectively. They show that GE with NS, without any memory of past individuals, using any of the four behavioral descriptors, clearly outperforms standard fitness based GE in terms of hits rate for BNF-Koza, which is semantically equivalent to the original SFT problem. Standard GE for BNF-O'Neill, which defines a biased narrower search space, had a high hit percentage but was also outperformed by NS-GE for every behavior descriptor. NS-GE was also able to find more efficient programs (requiring less number of steps) than standard GE in both grammars. Anyhow, in spite that NS-GE with Steps Sequence descriptor found the most efficient solution, we cannot say that any of those descriptor is more efficient than the other: chance can play a role here, on average the number of required steps is very similar. Successful solutions evolved by NS-GE required a less number of evaluations, for both grammars (confirmed by the values on the Gen column in both tables). The average number of food items eaten is much higher in the NS-GE for every descriptor but that comes naturally from the higher success rate.

Even a simple descriptor that defines a very small behavior space (90 behaviors), and which is highly related with the fitness function: just counting the amount of food eaten in the end of the 650 steps, was able to attain a remarkable success rate. When we increase the number of samples (granularity of behavior characterization), we have increased the behavior space but we were also able to distinguish behaviors that were considered similar with just one sampling. Note that the amount of food eaten can never decrease and

| BNF-Koza           | Hits | Food  | Gen   | Steps  | MinSteps |
|--------------------|------|-------|-------|--------|----------|
| Fitness (GE)       | 8%   | 58.8  | 37.75 | 589.25 | 497      |
| Food <sub>1</sub>  | 42%  | 78.36 | 22.55 | 599.38 | 385      |
| Food <sub>26</sub> | 48%  | 81.96 | 28.38 | 584.90 | 461      |
| Food Seq.          | 33%  | 76.59 | 30.28 | 575.10 | 385      |
| Steps Seq.         | 41%  | 77.88 | 23.78 | 587.92 | 331      |

| BNF-O'Neill        | Hits | Food  | Gen   | Steps  | MinSteps |
|--------------------|------|-------|-------|--------|----------|
| Fitness (GE)       | 77%  | 82.92 | 15.84 | 613.99 | 609      |
| Food <sub>1</sub>  | 95%  | 88.28 | 08.96 | 614.01 | 607      |
| Food <sub>26</sub> | 100% | 89.00 | 08.19 | 614.06 | 607      |
| Food Seq.          | 94%  | 88.24 | 09.64 | 613.87 | 607      |
| Steps Seq.         | 95%  | 88.28 | 08.96 | 614.01 | 607      |

Table 2: Results for BNF-Koza and BNF-O'Neill. For each behavior descriptor and objective based fitness, the columns give the percentage of hits, the average number of food items eaten, the average number of generations for a hit, the average and minimal number of steps for a hit.

26 samples imply sampling every 25 steps, which in combination with the form of the Santa Fe Trail impose strong constraints on the possible values of consecutive cells. The increase on the behavior description granularity has increased the performance in both grammars, but more experiments need to be made in order to assess if a too granular description is not necessary, distinguishing a lot of irrelevant behavior and slowing down evolution.

Considering all evolved programs in our experiments, the evolved code presented in Fig. 6 was able to complete the trail in the least number of steps: 331. This program outperforms the most efficient program known so far, evolved by the Constituent Grammatical Evolution algorithm (CGE) (Georgiou and Teahan, 2011). Note that CGE has attained a higher hit rate than NS-GE, but CGE is a much more complex algorithm than the standard GE, incorporating the concepts of constituent genes and conditional behavior switching, being able to decrease the actual search space, and explore programs in more useful areas. With a slight modification over the standard GE, using very intuitive behavior characterizations, by rewarding individuals that behave differently from the others, without any selective pressure to find the better ones, NS-GE has improved dramatically the performance on the very deceptive Santa Fe Trail Problem.

## Conclusion and Future Work

Even though Grammatical Evolution shows competence on a series of problems where it has been applied, its effectiveness and efficiency on deceptive problems, such as the Santa Fe Trail, has been questioned (Robilliard et al., 2005). This is because problems of this type have some characteristics of real world problems, such as many local optima and large

search spaces, making them challenging and difficult for evolutionary algorithms to efficiently solve them (Langdon and Poli, 1998; O'Neill and Ryan, 2003). This work presented the first application of Novelty Search in Grammatical Evolution and benchmarked this approach in the Santa Fe Trail problem to investigate whether a search mechanism, which promotes behavioral novelty, would improve the performance of Grammatical Evolution in a deceptive problem. The results demonstrated a dramatic improvement in terms of both success rate and quality of solutions, which encourages further investigation and application to more problems such as Los Altos Hills and Maze Searching. Furthermore, more work is required for the investigation of how the application of Novelty Search in Grammatical Evolution affects the genotype and phenotype bloating, a known issue with the Santa Fe Trail problem.

# Quantifying the Impact of Parameter Tuning on Nature-Inspired Algorithms

Matthew Crossley, Andy Nisbet and Martyn Amos

Manchester Metropolitan University, Manchester M1 5GD, UK.  
Email: m.crossley@mmu.ac.uk

## Abstract

The problem of *parameterization* is often central to the effective deployment of nature-inspired algorithms. However, finding the optimal set of parameter values for a combination of problem instance and solution method is highly challenging, and few concrete guidelines exist on how and when such *tuning* may be performed. Previous work tends to either focus on a specific algorithm or use benchmark problems, and both of these restrictions limit the applicability of any findings. Here, we examine a *number* of different algorithms, and study them in a “problem agnostic” fashion (i.e., one that is not tied to specific instances) by considering their performance on *fitness landscapes* with varying characteristics. Using this approach, we make a number of observations on which algorithms may (or may not) benefit from tuning, and in which specific circumstances.

## Introduction and Background

There exist many algorithms that are inspired by nature, and each has associated with it a set of *parameters*. These define specific features or details of an algorithm that may be altered in order to change the behaviour or performance of the method (for example, in evolutionary algorithms, parameters may include mutation rate or crossover probability). The problem of finding the optimal settings for these parameters (often referred to as “tuning”) is well-established (Lobo et al., 2007; Nannen et al., 2008; Akay and Karaboga, 2009; Birattari, 2009; Eiben and Smit, 2011), but little in-depth work has been performed on quantifying the *benefits* of tuning for a *range* of algorithms. We address this in the current paper, by investigating the precise benefits (or otherwise) of tuning for a number of different algorithms. Moreover, we do this in a way that is independent of any specific *problem*, by using an approach based on fitness landscape characteristics. The main contribution of the paper is therefore to establish a framework for deciding - prior to any problem-specific implementation - which algorithms may (or may *not*) benefit from tuning. Our aim is to offer advice to future practitioners on the relative merits of tuning, compared to the effort involved in finding the best set of parameter values. We achieve this by establishing, for each

algorithm, the problem features that offer the most *potential* for performance improvements via tuning.

Previous work (Crossley et al., 2013) characterised a number of nature-inspired algorithms according to their performance on fitness landscapes with different features. However, the authors used the *default* parameter settings for each algorithm, which fails to reflect the fact that, in practice, methods are usually *tuned* prior to serious use (Leung et al., 2003; Adenso-Diaz and Laguna, 2006; Koster and Beney, 2007; Ridge and Kudenko, 2010). Here, we extend this work by quantifying the relative merits of tuning for a range of algorithms in a wide variety of fitness landscape scenarios. We achieve this by assessing both their tuned and untuned behaviour, using the methods described in Crossley et al. (2013).

In order to tune our selected algorithms, we use the notion of *racing*, which was first introduced in the field of machine learning (Maron and Moore, 1993, 1997). Specifically, we use the F-race algorithm (Birattari et al., 2002; Yuan and Gallagher, 2004; Smit and Eiben, 2009; Birattari et al., 2010), which has been extensively used to find the best possible set of parameter values for a given problem in a limited time.

The rest of the paper is organised as follows: we first describe our approach in the Methodology section, before presenting our experimental findings in the Results section. We conclude with a discussion of the implications of our results, and suggest further work.

## Methodology

Our methodology may be summarised as follows: (1) select a number of nature-inspired algorithms, and obtain consistent source code for their implementation; (2) for each algorithm, find the best parameter settings (i.e., tune) over a number of different problems; (3) compare the performance of tuned and untuned algorithms.

### Algorithm selection

We compare a number of nature-inspired algorithms, all of which are commonly applied to continuous function opti-

misation (we use the same set as in Crossley et al. (2013)). These may be classified (Brabazon and O'Neill, 2006) as either *social*, *evolutionary* or *physical*. The social algorithms we select are Bacterial Foraging Optimisation Algorithm (BFOA) (Passino, 2002), Bees Algorithm (BA) (Pham et al., 2006), and Particle Swarm Optimisation (PSO) (Kennedy and Eberhart, 1995). The evolutionary algorithms selected are Genetic Algorithms (GA) (Goldberg, 1989) and Evolution Strategies (ES) (Bäck and Schwefel, 1993), and physical algorithms are represented by Harmony Search (HS) (Geem and Kim, 2001). We also include stochastic hill climbing (SHC) as a “baseline” algorithm; in contrast to Crossley et al. (2013) we exclude random search, as it has no parameters to tune. As before, we heed the observation that “Ideally, competing algorithms would be coded by the same expert programmer and run on the same test problems on the same computer configuration” (Barr et al., 1995). With that in mind, we use only implementations provided by Brownlee (2011). Space prevents a complete description of specific implementation details for each algorithm, but full implementation details can be found in Brownlee (2011), which is freely available and contains complete source code.

## Tuning

Our fundamental goal is to investigate the pre- and post-tuned performance of our selected algorithms on landscapes with different general features, and thus identify characteristics of landscapes for which tuning may yield significant differences in algorithm performance. As Morgan and Gallagher (2010) observe, “Different problem types have their own characteristics, however it is usually the case that complementary insights into algorithm behaviour result from conducting larger experimental studies using a variety of different problem *types*” (our emphasis). Rather than using arbitrary benchmark instances of problems in order to perform tuning, we use a landscape-based approach, as utilised in Crossley et al. (2013). As Morgan and Gallagher (2010) explain, this Max-Set of Gaussians (MSG) method (Gallagher and Yuan, 2006) is a “randomised landscape generator that specifies test problems as a weighted sum of Gaussian functions. By specifying the number of Gaussians and the mean and covariance parameters for each component, a variety of test landscape instances can be generated. The topological properties of the landscapes are intuitively related to (and vary smoothly with) the parameters of the generator.” We now describe the characteristics under study:

*Ruggedness* of a landscape is often linked to its difficulty (Jones and Forrest, 1995), and factors affecting this include (1) the *number* of local optima (Horn and Goldberg, 1994), and (2) *ratio* of the fitness value of local optima to the global optimal value (Malan and Engelbrecht, 2009; Merz, 2000). Other significant factors concern (3) *dimensionality* (Hendtlass, 2009) (that is, the number of variables in the objective function), (4) *boundary constraints* (that is, the limits im-

Table 1: A summary of the ranges selected for the various characteristics in the landscape generation methodology.

| Characteristic                          | Min | Max | Step | Default |
|-----------------------------------------|-----|-----|------|---------|
| No. of local optima                     | 0   | 9   | 1    | 3       |
| Ratio of local optima to global optimum | 0.1 | 0.9 | 0.2  | 0.5     |
| Dimensionality                          | 1   | 10  | 1    | 2       |
| Boundary constraints                    | 10  | 100 | 10   | 30      |
| Smoothness                              | 10  | 100 | 10   | 15      |

posed on the value of a variable) (Kukkonen and Lampinen, 2005), and (5) *smoothness* of each Gaussian curve (effectively the gradient) used to generate the landscape (Beyer and Schwefel, 2002) - a smaller value indicates a smoother gradient. For each characteristic, we use the same ranges as in Crossley et al. (2013), summarised in Table 1.

To produce a test set of problems, we use the MSG landscape generator. For every value of every characteristic (in the range specified in Table 1) we generate a set of five landscapes, which makes up the initial problem set for each value. We then use the F-racing methodology (Birattari et al., 2002) to find optimised parameters for each algorithm, over *every* value of *every* landscape characteristic used. We ensure that termination criteria are standardised, in order to ensure reasonable comparisons, and therefore use the number of objective function evaluations to determine when to terminate an algorithm’s run. We established, through initial experiments, that all selected algorithms generally converge within 20,000 objective function evaluations, so we use that as the specific value.

## Comparison

We run each algorithm 100 times on each landscape in the set of landscapes generated for each particular characteristic value (when investigating smoothness, for example, we generate 1000 different landscapes (100 each for smoothness = 10 ... 100), and run each algorithm 100 times on each landscape). This is done first for all algorithms with ‘default’ parameter configurations, and then again, this time using the parameter configurations obtained through the F-Racing process. We measure the performance of each algorithm in terms of the mean ( $\mu$ ) and standard deviation ( $\sigma$ ) of the exact average error obtained, over all values for a particular characteristic. That is, we investigate the *robustness* of each algorithm to changes in the values for each characteristic, rather than their absolute performance on specific problem instances. This allows us to identify specific landscape features where tuning may make a significant difference, some difference, or no difference at all, for a particular algorithm.

## Results

We find that the effect of tuning using F-Racing is varied across algorithms, and that they fit into three categories: Algorithms which *do not* benefit from F-Racing (ES), algorithms which only benefit significantly from F-Racing when a landscape is ‘difficult’ for the algorithm using default parameters (BA, HS, PSO), and algorithms which *always* benefit from F-Racing (BFOA, GA, SHC). Of course, we acknowledge the fact that F-Racing is just one of many possible meta-search techniques available for parameter tuning, and future work will involve a comparative study of alternative methods.

We summarise our results in Table 2; the full datasets are available online<sup>1</sup>; the repository contains all performance data across all runs, summary spreadsheets and details of all parameter settings. We now examine in detail the performance of each algorithm, using spider plots to graphically depict the results in Table 2. For each plot, the further a line is from the origin, the *smaller* the average error (that is, the “larger” an area, the larger the degree of robustness, which is considered “better”).

### Bacterial Foraging Optimisation Algorithm

There exists little discussion on the role of different parameters in the BFOA. While some elements of the search pattern are clearly altered by various parameters, it is very difficult to estimate values for these. In the original description of the BFOA (Passino, 2002), the parameter values were assigned based on observation of actual bacterial colonies. While this may be true to the nature-inspired concept, it is not necessarily the best way to obtain optimal performance from the algorithm. The combination of parameters offered by BFOA gives a highly configurable search environment. Parameters such as step size and population size directly affect the potential area the algorithm can explore in a given number of objective function calculations. Attraction and repulsion weights, and the “space” over which these attraction and repulsion effects spread, work to control local optima avoidance. Parameters controlling the number of chemotactic steps before a reproduction step, and the number of reproduction steps before an elimination-dispersal event, control the balance of *exploitation* versus *exploration*. Given that the search behaviour of the algorithm is highly configurable, it is unsurprising that BFOA is heavily reliant on tuning. Results for BFOA are shown in Figure 1. Across all characteristics, tuning offers a *significant* improvement on the average error and standard deviation of the performance - in many cases, improving the ranking of the algorithm from the largest average error to one of the smallest, and coping well with the changing characteristics. We see the most significant improvement where boundary constraint ranges change, a characteristic that is heavily reliant on parameters

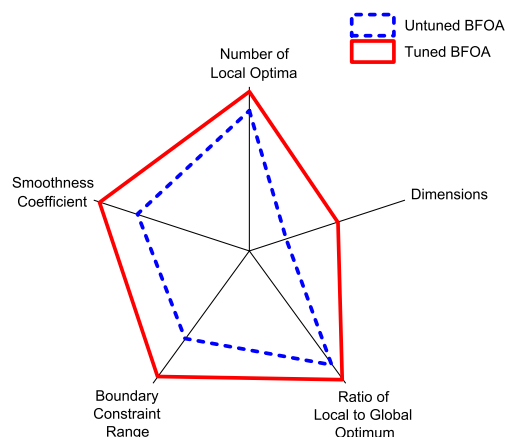

Figure 1: Summary of results for **Bacterial Foraging Optimisation Algorithm**.

which control the range at which new solutions are generated (in the case of BFOA, this is the *step size*). Improvements are also shown for dimensionality and smoothness coefficient, increasing the performance of BFOA where there is little gradient information in a large fitness landscape. Smaller improvements are demonstrated by the increasing number of local optima and the increasing attractiveness of these local optima, but tuning still benefits the algorithm considerably.

In terms of the configurations selected by F-Racing, there is little variation in parameter values as characteristics change. Across all characteristics, and all values for those characteristics, there are only eight different configurations selected by racing. This suggests that, while it is difficult to find a *good* configuration, once it has been found, it is likely to be good for all *similar* problems. Tuning is vital to the performance of the BFOA, but it is possible that by exploring problems using a similar methodology to that demonstrated here, we may create a ‘bank’ of promising configurations.

### Bees Algorithm

The BA is considered to be an algorithm on which parameterisation has little effect (Pham et al., 2006). We observe that the BA is one of the best *untuned* performers in this study, offering weight to this argument for relative parameter insensitivity. In terms of adjusting the BA to cope with an increasing number of local optima, there are several parameters which have an effect. Parameters such as the *number of sites* under investigation, the *number of bees* attributed to those sites, and the *differentiation* between sites and ‘elite’ sites are all factors which affect the searching behaviour of the algorithm to allow for greater flexibility as the modality of the problem landscape increases. Results for BA are

<sup>1</sup><http://dx.doi.org/10.6084/m9.figshare.696908>

Table 2: Mean ( $\mu$ ) and standard deviation ( $\sigma$ ) of the exact average error of algorithm performance (both untuned (UT) and tuned (T)). Smaller values imply more robustness to changes in a specific characteristic.

 Figure 2: Summary of results for **Bees Algorithm**.

shown in Figure 2. Post-tuning, we find that the BA selects the *same* parameter configuration, regardless of the number of local optima present in the landscape. We then see that tuning has no effect on the ability of the algorithm to cope with increasing numbers of local optima. As long as the number of sites under investigation is greater than the number of optima, the algorithm is capable of dealing with modality. Coupled with the abandonment of ‘unpromising’ sites, this means that ‘too many’ sites are not detrimental to the exploration pattern of the algorithm.

We see the same pattern when increasing the ratio of local optima to the global optimum. As long as the number of sites under investigation covers the modality of the landscape, the BA is not hampered by increasing levels of attractiveness, regardless of parameter settings. The *patch size* parameter of the BA controls the distance from a site bees are allowed to explore. This is the parameter which affects the search behaviour of the algorithm as boundary constraint size increases. The BA allows for full coverage of any sized search space, using *scout bees* to investigate new random sites to give ‘teleportation’ across the landscape. As with the number of local optima, we find the F-Races for the BA

 Figure 3: Summary of results for **Evolution Strategies**.

select the same parameter set for most boundary constraint sizes. We find that, post-tuning, the performance of the BA actually *decreases* slightly, suggesting the algorithm can cope less well with changes in boundary constraint size. We believe that the configurations may have become over-fitted to the landscapes used for tuning, and, while performance on the landscapes used for racing may have increased, the ability to search generalised landscapes has decreased. Dimensionality provides the most significant result in terms of pre-tuning and post-tuning performance of the BA. We observe little change in performance at one to three dimensions - the point where the untuned algorithm is already performing well. As dimensionality increases beyond this, the effect of tuning becomes *increasingly* beneficial. We suggest that there is no increase in performance in other characteristics because these landscapes are *not challenging enough* to the BA to require adjusting the parameters. For the ranges of landscape characteristics on which we have tested the BA, it is clear that tuning generally makes little difference to the performance, as suggested by its original developer.

## Evolution Strategies

ES has the smallest number of parameters of all the algorithms studied here (excepting the baseline algorithm, stochastic hill climbing). The two parameters this form of ES offers are (1) *population size* and (2) *number of children*. It is suggested (Cant-Paz, 2001) that altering these parameters adjusts *selection pressure* (that is to say, the *greediness* of the algorithm changes). The parameter configurations obtained through F-Racing are varied, implying that there do exist some configurations that are more successful than others. A range of configurations are selected across each characteristic - both in terms of different values for the two parameters, and different selection pressures when the two parameters are combined. Results for ES are shown in Figure 3. It is perhaps surprising to observe that the results of using the tuned parameters show little or no change in performance across all characteristics. There is a small decrease in average error as the number of local optima changes, but the standard deviation is similar for both untuned and tuned, suggesting that while the average error has decreased very slightly, the ability of the algorithm to cope with increasing numbers of local optima is unchanged. For all other characteristics post-tuning, there is little change in both average error and standard deviation across characteristics values (that is to say, the algorithm is no more capable of dealing with changes in these characteristics). This is perhaps consistent with the definition of the two parameters the algorithm offers - selection pressure can only affect the way in which ES explores local optima, and there is no control over the area that is explored around each point of interest, or any way to encourage the algorithm to rapidly explore an increasingly large search space.

We use a simple variant of ES, here, and there exist many other versions of the ES algorithm that offer a greater range of parameters (such as CMA-ES (Hansen and Kern, 2004)). ES clearly yields its best performance with an “out-of-the-box” parameter configuration, which means that it is quick to implement. However, our results suggest that there is little that can be done to improve the performance of this particular variant.

## Genetic Algorithm

The performance of the GA increases post-tuning, coping significantly better with increasing numbers of local optima, increasing boundary constraint range and an increasing smoothness coefficient. Results for the GA are shown in Figure 4. The parameters of the GA are not as intuitively linked to the exploration pattern as many of the other algorithms in the study. This particular GA offers four configurable parameters: (1) *population size*, (2) *‘bits’ per parameter* in the representation, (3) *crossover rate* and (4) *mutation rate*. In experiments with a fixed number of objective function calculations, population size affects the number of generations the algorithm evaluates before terminating. A

Figure 4: Summary of results for **Genetic Algorithm**.

larger number of bits in a bit string representation allows more ‘precise’ solutions to be generated at the expense of having a representation which is less affected by mutation. Similarly to BFOA, there are a few configurations which re-occur across different characteristics and different characteristic values. It is probable that once a ‘good’ configuration has been found for a GA, it is applicable to ‘similar’ landscapes, which is consistent with the suggestion Goldberg (1989) that GAs are robust problem solvers, exhibiting approximately the same performance across a wide range of problems.

With increasing dimensionality, the GA initially shows promising results in terms of tuned performance, with a marked performance increase up to four dimensions. The benefit from tuning rapidly declines, however, until the tuned performance is *worse* than that of the untuned version. There are two possible explanations for this: the first is that the restriction on the number of objective calculations did not allow the F-Race algorithm to gather any meaningful performance data from the configurations. The second explanation is that we did not test a wide enough range of configurations - although two of the four parameters have definite ranges (mutation and crossover rates are percentages, thus generation was bounded between zero and one), so this is unlikely.

## Harmony Search

The four parameters of HS all control different aspects of the search strategy. *Memory size* dictates how many promising solutions can be stored - effectively, how many potential sites of interest are retained by the algorithm. *Consideration rate* and *adjustment rate* control how new solutions are generated. The consideration rate is the percentage chance that a solution based on one in memory will be generated (conversely, *1-consideration rate* is the chance a random so-

Figure 5: Summary of results for **Harmony Search**.

lution is generated instead). The adjustment rate is then the percentage chance that the randomly chosen solution from memory will be adjusted. If so, the fourth parameter, which controls the *maximum range* at which solutions can be adjusted, is used. If the adjustment does not occur, the considered solution potentially occupies an additional slot in the memory - thus increasing the chance that this solution may be chosen for consideration again. The interplay between these parameters is crucial, and it is somewhat hard to see how consideration rate and adjustment rate can directly affect the search strategy - unlike memory size and range, which are more obvious. The results for HS are shown in Figure 5. HS, like the BA, offers some of the lowest ‘out of the box’ average error rates in this study. For most characteristics, there is little room for a performance increase post-tuning. Boundary constraint range proves to be the second-most challenging characteristic to HS pre-tuning, but post-tuning shows improved performance. The range values in all the configurations selected by F-Racing are much smaller than those in the ‘out of the box’ values, and this contributes significantly to the performance improvement when boundary constraint ranges are increasing. The consideration rate also decreases almost linearly as size increases - effectively, more random solutions are used instead of relying on the ‘memory’. These random solutions allow the solution pool to jump from one position in the search space to another, encouraging a wider search space, and explaining the significant improvement as boundary constraint range increases. Dimensionality also yields an improvement in the tuned parameter performance of HS, in terms of both average error and ability to cope, as it rises. High dimension problems (seven and above) have a much higher consideration rate than the successful configurations for lower dimensionality, suggesting that a focus on *exploitation* rather than *exploration* is beneficial to the HS when dimensionality is high.

This is the opposite case of what happens with boundary constraint range, as discussed above.

## Particle Swarm Optimisation

PSO in this form has four parameters; these control the *population size*, the *maximum velocity* of a particle, the bias towards the *particle best solution* and the bias towards the *global best solution*. With these parameters, it is possible to control the coverage of a search space (the number of particles), enforce a large search area of a small search area for each particle (the maximum velocity), and, through manipulation of the local and global best solution bias, control the capability of the algorithm to converge on a single solution or explore several areas of interest (optima avoidance). Results for PSO are shown in Figure 6. The parameters used cover a broad range of search behaviours, and, as such, we would expect to see a large improvement in particle swarm performance post-tuning. This holds true for most of our characteristics. Results for the number of local optima, for example, show a reasonable decrease in average error as the number of local optima increases, yet the standard deviation demonstrates no change, indicating that the algorithm is no more capable of dealing with increasing numbers of local optima post-tuning. Performance of PSO greatly improves on dimensionality post-tuning, in terms of both average error and ability to cope as it grows. The F-Race algorithm for PSO selects the same configuration for all values of dimensionality (except for 2 dimensions), implying that there is no specific parameter that requires adjustment to cope with the increase in dimensionality, but selecting a configuration which provides good *exploration* allows PSO to perform well as the size of the search space increases exponentially. This trend continues across all characteristics, with F-Races often selecting the same configurations, regardless of characteristic values. As with the other swarming algorithms, we suggest that once a good configuration has been found, it is able to deal with a wide range of problems of a similar nature, regardless of the specific characteristics. The configurations selected are all varied in their parameters, and it is unexpected to see that there is no pattern to maximum velocity as boundary constraint range increases. This is possibly because maximum velocity is an upper bound, and there are particles with randomly generated velocities below the maximum, so this parameter is less significant than it may initially appear. It would perhaps be interesting to consider the effect of having a *minimum* velocity on the increase in boundary constraint range, although this would also severely hamper exploitation.

## Stochastic Hill-Climbing

With only a single parameter - the *range* at which new solutions are generated - the SHC algorithm does not offer a large amount of customisation. This single parameter is directly linked to the search pattern and nothing else, and as

Figure 6: Summary of results for **Particle Swarm Optimization**.

there are no other parameters there is no interplay between parameters to consider. Arguably, therefore, SHC should prove the easiest algorithm to tune. Results for SHC are shown in Figure 7. All characteristics, barring dimensionality, show an improvement post-tuning. As the neighbourhood size is the range at which new solutions are generated, it is unsurprising that tuning improves algorithm performance as boundary constraint ranges change. As the number of objective function calculations is limited, despite having a larger neighbourhood size, the ability of the algorithm to effectively explore larger environments is still restricted, therefore the average error does not decrease by as much as may be expected, and the ability of the algorithm to deal with increasing search space sizes improves only slightly. SHC demonstrates a large increase in performance and a greater ability to cope with more optima (a reduced standard deviation) post-tuning. The parameter configurations selected for the number of local optima, the ratio of local optima *and* the smoothness all have a neighbourhood size of around 50% of the search space size. We suggest that the performance improvement for all of these characteristics is actually derived from the algorithm having configured itself properly for the search space size used as a default for all other characteristics, rather than tuning itself to best perform on any specific characteristic.

## Conclusions and Future Work

In this paper we have built on previous studies of the performance of nature-inspired algorithms on fitness landscapes with different characteristics. Earlier work explored ‘out of the box’ parameter configurations, and we further develop this by using an automated parameter configuration methodology. This allows us to study the effect of tuning on different algorithms, contributing significantly to the debate on

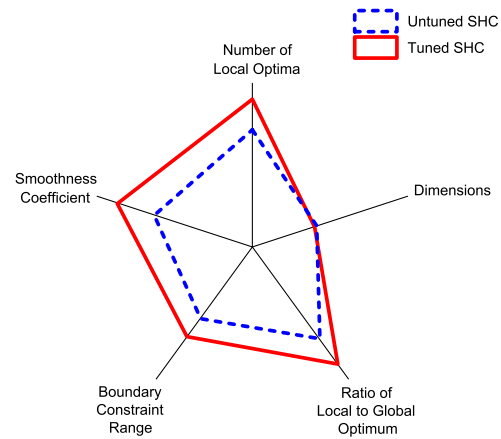

Figure 7: Summary of results for **Stochastic Hill-Climbing Algorithm**.

when and how it is beneficial to tune specific algorithms.

We observe that algorithms broadly fall into three categories: algorithms which *do not/sometimes/always* benefit from tuning by F-Racing. Dimensionality often offers the most significant improvement post-tuning in algorithms, particularly those with parameters that increase the *breadth* of search space (swarming algorithms are significantly better here than evolutionary algorithms). The methodology presented here is easy to implement, is computationally inexpensive, and offers considerably more information on the performance of an algorithm than using a standard set of benchmark problems. We hope that it will offer a framework for the experimental comparison of nature-inspired algorithms, as well as a useful set of heuristics for practitioners to use in order to decide when and how to tune their methods. Future work will focus on a comparative study of tuning techniques (i.e., in addition to F-Racing), and the application of our insights to the predictive performance ranking of methods on given problems.

## Abstract

The Genetic Immune Strategy for Multiple Objective Optimization (GISMOO) is a hybrid algorithm for solving multiobjective problems. The performance of this approach has been assessed using a classical combinatorial multiobjective optimization benchmark: the multiobjective 0/1 knapsack problem (MOKP) [1] and two-dimensional unconstrained multiobjective problems (ZDT) [2]. This paper shows that the GISMOO algorithm can also efficiently solve the multiobjective quadratic assignment problem (mQAP). A performance comparison carried out using well-known published algorithms and shows GISMOO to advantage.

## Introduction

Even today, most of the work on optimization treats problems with a single objective to optimize [3, 4]. However, practical contexts have a multiobjective nature inherent in various performance measures. For this type of problems, there is generally no ideal solution which gives optimality for all the objectives. This is why the optimal solution concept becomes less relevant and is replaced by Pareto-optimality, where we obtain a set of solutions giving us a compromise among the different objectives. The solutions cannot be prioritized except by the decision maker's preferences. Multiobjective problems also often have a very large feasible solution set and are characterized by repetitive decisions. Consequently, we can define two goals in multiobjective optimization: (i) to discover solutions as close to the Pareto-optimal solutions as possible; and (ii) to find solutions as diverse as possible in the solution set thereby obtained. Satisfying these two goals is a challenge for any multiobjective algorithm [5-10].

Many authors have concluded that a promising research model for multiobjective problem solving is that of metaheuristics adaptation [11, 12]. In fact, these algorithms are among the greatest achievements of modern operations research, especially in solving large and complex real problems [13-15]. According to Whitacre [13], the growing interest in metaheuristics in the last few years is due to the successful adaptation of these algorithms to specific problems and hybrid approaches.

Many of the algorithms proposed for multi-objective problems are Evolutionary Algorithms (EA) [6, 8, 16-19]. This is so, doubtlessly because EA's can traverse a large search space to generate an approximation of the Pareto-optimal front in a single optimization step [20]. One of these algorithms, proposed by [21], is a hybrid between a Genetic Algorithm (GA) and an Artificial Immune System (AIS). This approach, called GISMOO, has a small number of parameters to calibrate, is easy to implement, and has been shown to be efficient in solving classical benchmarks in both discrete and continuous optimization.

The goal of this paper is to deepen the understanding of the Quadratic Assignment Problem (QAP) from the Pareto viewpoint, by adapting the GISMOO algorithm to solve this problem. On the one hand, we mean to show that this is an interesting approach in the solution of the multiobjective Quadratic Assignment Problem (mQAP). On the other hand, because only a few workers have treated this problem from a Pareto viewpoint, we wish to compare the performance of GISMOO with that of other known algorithms.

The remainder of this paper is organized as follows. Section II briefly describes the mQAP. In Section III we present the GISMOO algorithm in order to solve the problem in a Pareto sense. Section IV details the numerical experiments carried out in this paper. Section V compares the experimental results of GISMOO with those of two other evolutionary algorithms well known in the literature: NSGAII and PMS<sup>MO</sup>. The last section offers some concluding remarks.

## The multiobjective Quadratic Assignment Problem (mQAP)

The Quadratic Assignment Problem (QAP), defined by Koopmans and Beckmann [22] in 1957, is one of the most well known and widely studied problems of combinatorial optimization. It consists of assigning  $n$  interconnected facilities (factories, warehouses, etc.) to  $n$  locations in such a way as to minimize the sum of the product flows over the distances. The problem can be formulated as follows:

$$\text{Minimise } C(\pi) = \sum_{i=1}^n \sum_{j=1}^n a_{ij} b_{\pi_i \pi_j} \quad (1)$$

where  $n$  is the number of locations/facilities,  $a_{ij}$  is the distance between location  $i$  and location  $j$ ,  $b_{ij}$  is the flow between facilities  $i$  and  $j$ , and  $\pi_i$  is the location of facility  $i$  in the permutation  $\pi \in \Omega$  where  $\Omega$  is the problem's solution space. The QAP belongs to the class of NP-hard problems [23, 24].

The multiobjective Quadratic Assignment Problem (mQAP) was formalized in 2002 [25]. This particular extension of the QAP considers several flow matrices between any two facilities. The mQAP can therefore model the situation of installations where the management of several types of products is a concern. For example, the flow of doctors, patients, visitors, pharmaceutical products, equipment, etc., between different facilities can be considered in the implantation of a (new) hospital. The mQAP can be formalized by the following equations:

$$\text{Minimise } \{C(\pi)\} = \{C^1(\pi), \dots, C^m(\pi)\}, \pi \in \Omega \quad (2)$$

with

$$C^k(\pi) = \sum_{i=1}^n \sum_{j=1}^n a_{ij} b_{\pi_i \pi_j}^k, k = 1, \dots, m \quad (3)$$

where  $m$  is the number of objectives (i.e. flow types),  $C(\pi)$  is the objective function vector to be simultaneously optimized,  $b_{\pi_i \pi_j}^k$  is the  $k$ -th flow between the facilities  $\pi_i$  et  $\pi_j$ , and *minimizing* means finding all non-dominated points [23]. Some research focuses on the resolution of mQAP [26-31].

## Genetic Immune Strategy for MultiObjective Optimization (GISMOO)

GISMOO is a hybrid Pareto GA/AIS algorithm which offers an original iterative process in two phases: a Genetic phase and an Immune phase. New solutions (also called descendants) are then obtained from the offspring creation using classical genetic operators and from the creation of clones according to the AIS cloning selection principle.

As for most multiple objective evolutionary algorithms, one of the main difficulties in solving multiple objective problems is the performance assignment. Indeed, the quality of a solution in multiobjective optimization depends on the evaluation of multiple incommensurable and often competing objective functions. Then, instead of dealing with the real objective functions the performance assignment of a Pareto EA can schematically be viewed as being composed of two factors: a *dominance factor* and an *isolation factor* [9]. The first factor evaluates the dominance level of a given solution in Pareto sense and the second factor measures the density of solutions surrounding a given solution. Even if the performance assignment of most Pareto EAs is done using these two factors, each algorithm calculates the two factors in different ways.

Regarding GISMOO, the dominance factor is calculated in two steps as proposed in [9]. The first step consists of assigning to each individual  $x$  of the Parent population ( $POP$ ) combined with the Descendant population ( $Q$ ), a strength  $S(x)$  corresponding to the number of solutions dominated by  $x$ . A solution  $x$  is said to *dominate* a solution  $y$  if and only if  $\exists i \in Z \mid f_i(x) < f_i(y)$ , and  $\forall j \in Z, j \neq i \mid f_j(x) \leq f_j(y)$  where  $f_i(\cdot)$  indicates the value of the solution for the objective  $i$  and  $Z$  indicates the number of objectives to minimize. Using the value of  $S(x)$ , the dominance factor of an individual  $x$ , called  $R^+(x)$ , is determined in GISMOO using Equation (4) below, where  $\succ$  indicates a dominance relationship of  $y$  with respect to  $x$ .

$$R^+(x) = \begin{cases} \frac{S(x)}{1 + 2 * S(x)} & \text{if } \sum_{y \in POP \cup Q, y \succ x} S(y) = 0 \\ \sum_{y \in POP \cup Q, y \succ x} S(y) & \end{cases} \quad (4)$$

In this way, for the non-dominated individuals  $x$  for which  $\sum_{y \in POP \cup Q, y \succ x} S(y) = 0$ , the dominance factor value is not

equal to 0, but rather between 0 and 0.5 according to the number of solutions it dominates. For the non-dominated solutions, this computation of the dominance factor allows us to better take into account the distribution of dominated solutions of  $POP$  and  $Q$  within the search space. Thus, the computation of the dominance factor favours non-dominated solutions situated in the less well explored regions.

The isolation factor, for its part, is based on the space metric  $sp$  introduced by Schott [32], which measures the distance  $Dist(x)$  between a given individual  $x$  and its closest neighbour  $y$  (with  $x \neq y$ ) as indicated in Equation (5).

$$Dist(x) = \min_{y \in POP \cup Q} \left[ \sqrt{(f_1(x) - f_1(y))^2 + \dots + (f_z(x) - f_z(y))^2} \right] \quad (5)$$

It should be noted that, in GISMOO, the isolation factor value is not directly added to the dominance factor value. In fact, the fitness of an individual in GISMOO is obtained using the dominance factor. and in case of a tie between individuals, the tie is broken using the isolation factor.

GISMOO's outline is shown in Algorithm 1. The algorithm starts building an initial population ( $POP_0$ ) of size  $N_1$  randomly or using greedy heuristics.

The main loop of GISMOO (lines 3-21) begins with the Genetic phase (lines 4-8) and generates  $N/2$  offspring. This phase consists of the classical operations of a GA: selection, crossover and mutation. Notice that the selection procedure used in GISMOO is a binary tournament selection. In addition, even if two offspring are created during the recombination, only the best of the two is added to the Descendant population  $Q$ . It is important to mention that no crossover probability is needed in the Genetic phase of GISMOO, because the number of offspring to generate is related to the Parent population size. However, a mutation probability ( $p_m$ ) is used to determine whether the generated offspring will be mutated or not (line 6). The crossover operator used in the Genetic phase to solve the mQAP problem is a cycle crossover operator [33] as proposed by [27]

for the same problem. For the mutation operator we choose to use a classical inversion operator.

---

**Algorithm 1** : Outline of GISMOO procedure
 

---

```

1: Create an initial Parent population  $POP_0$  of size  $N$ 
2: Initialize  $t$  to 1
3: While no stopping rules is invoked
4:   While  $|Q_t| < N/2$ 
5:     Select and recombine  $P_1$  and  $P_2 \in POP_t$  to obtain  $E_1$  and  $E_2$ 
6:     Mutate  $E_1$  and  $E_2$  according to mutation probability  $p_m$ 
7:     Evaluate  $E_1$  and  $E_2$  and add the best offspring found in  $Q_t$ 
8:   End While Genetic Phase
9:   Rank non-dominated solutions of  $POP_t$ 
10:  For each non-dominated solution  $x \in POP_t$  do
11:    Calculate  $nb\_clones_x$  to produce for  $x$  according to Eq. (6)
12:     $cpt = 0$ 
13:    While  $cpt < nb\_clones_x$ 
14:      Create 2 clones  $C_1^{clo}$  et  $C_2^{clo}$  using  $x$ 
15:      Create  $C_1^{hyp\alpha}$  (and  $C_2^{hyp\beta}$ ) by hyper-mutation  $\alpha(\beta)$  on  $C_1(C_2)$ 
16:      Evaluate  $C_1^{hyp\alpha}$  and  $C_2^{hyp\beta}$  and add the best of the two in  $Q_t$ 
17:       $cpt = cpt + 1$ 
18:    End While
19:  End For Immune Phase
20:  Copy the  $N$  first solutions of  $POP_t \cup Q_t$  into  $POP_{t+1}$ 
21:   $t = t + 1$ 
22: End While
    
```

---

Thereafter, the Immune phase (lines 9-19) adds  $N/2$  solutions to the Descendant population  $Q$ . These solutions are generated using the cloning selection principle introduced by De Castro and Timmis [34]. This principle is used to model the fact that only the best “antibodies” will proliferate in the population. In GISMOO, antibodies correspond to the non-dominated solutions of the current population  $POP$ . The number of clones to create for each non-dominated solution  $x$  ( $nb\_clones_x$ ) is related to the isolation factor as shown in Equation (6) :

$$nb\_clones_x = \text{round} \left[ \left( \text{Dist}(x) * \frac{N}{2} \right) / \sum_{x=1}^{nbSolND} \text{Dist}(x) \right] \quad (6)$$

where  $nbSolND$  indicates the total number of non-dominated solutions in the current population and  $\text{Dist}(x)$  corresponds to the isolation factor of an individual  $x$  as shown previously. The *round* function returns a number rounded to the nearest integer.

We note that a non-dominated solution in a less crowded region of the search space will generate a greater number of clones. This calculation is then dynamically adjusted during the iterative process of the algorithm and does not require the setting of additional parameters.

Once the number of clones to generate for an individual  $x$  is calculated, we generate two copies ( $C_1^{clo}, C_2^{clo}$ ) of  $x$ . Thereafter, the two clones are hyper-mutated using two different mutation operators  $\alpha$  and  $\beta$ , depending on the problem to solve, in order to obtain two mutated clones ( $C_1^{hyp\alpha}, C_2^{hyp\beta}$ ). The hyper-mutation rate to apply to all clones

generated for an individual  $x$  is set according to their rank. Indeed, for the first ten individuals with the highest rank the hyper-mutation rate is set at  $Z$ , the number of objectives to minimize. For each ten individuals the hyper-mutation rate is increased by one until we reach all non-dominated solutions. The two mutation operators used to solve the mQAP problem are respectively a classical inversion and a simple swap. We then compare the two obtained solutions, only adding the best in the Descendant population  $Q$ . This process is repeated until the total number of clones to be generated is reached.

After the Genetic and Immune phases, an elitist replacement of the population in order to keep the  $N$  best solutions of the combined Parent and Descendant population (line 20) is made. The replacement strategy used is a  $(\lambda + \mu)$  type of deterministic replacement where  $\lambda$  indicates the size of the Parent population and  $\mu$  the size of the Descendant population. In the proposed approach, we have  $\lambda = \mu = N$ . Finally, notice that GISMOO also used an archive in order to store non-dominated solutions found during the search. For a detailed description of GISMOO, the reader can consult Zinflou *et al.* [21].

## Numerical experiments

The focus of the experiments was on comparing the performance of GISMOO to those of two state-of-the-art algorithms: NSGAI [6] and PMS<sup>MO</sup> [9]. For a detailed description of these two evolutionary algorithms, the reader can respectively consult [6] [9].

### Test problems

We used a set of 22 benchmark mQAP instances to test the performance of the three evolutionary multiple objective algorithms. These test instances were generated by Knowles and Corne [25] and are available at <http://dbkgroup.org/knowles/mQAP/>. The number of locations, number of objectives and the category of each instance are indicated in Table 1.

### Experimental conditions

All the algorithms used in this work were implemented in C++ and compiled with Visual Studio .Net 2010, using the same main data structures in our implementation. All the algorithms use the same population size set at 100 individuals, and the same computational time for the same test instance. The computational times used for the instances with 10, 20, and 30 locations are set to 10, 20, and 30 seconds, respectively [27].

The parameter settings for NSGAI, PMS<sup>MO</sup> and GISMOO are determined empirically according to our previous works [1, 21] and the work of [27]. For the three algorithms, the mutation probability ( $p_m$ ) was set at 0.06. It is important to mention here that no crossover probability is required in the GISMOO algorithm. For the two other algorithms, the crossover probability was set at 1. The population size  $N$  is the same for all algorithms and was set at 100. To perform a recombination, all the algorithms in this paper use a cycle crossover operator [33]. As a mutation operator, each algorithm uses a classical inversion.

| Problem        | Instance category | # of locations | # of objectives |

Table 1: Characteristics of the test suites used

The computational experiments were run on a HP Z600 workstation with 2.13 GHz quad core Intel Xeon processor and 4 Gb of RAM, with Windows XP. Each instance was solved 30 times for each algorithm with random seeds.

### Performance assessment

The test procedure for performance assessment uses the generational distance (GD) metric [27]. This metric evaluates the average distance between the obtained non-dominated set ( $E$ ) and the reference set  $P^*$  of Pareto-optimal solutions or a very good approximation. The GD metric is computed using the following equation:

$$GD(E, P^*) = \frac{1}{|E|} \sum_{u \in E} \min\{dist(u, v) \mid v \in P^*\} \quad (7)$$

where  $dist(u, v)$  is the Euclidean distance (in objective spaces) between the solution  $u \in E$  and the nearest member  $v$  in  $P^*$  and  $|E|$  represents the cardinality of the set  $E$ . The smaller the value of this metric, the better the convergence toward the Pareto-optimal front. When all obtained solutions lie exactly on  $P^*$  chosen solutions, this metric has a value of zero.

The GD allows us to compare the preliminary results obtained by GISMOO to those of well known algorithms. However, it is obvious that additional performance assessments are needed in multiobjective optimization in order to prove conclusively the superiority of an algorithm. In this paper, the reference sets for the 10 location instances are the true Pareto front available at <http://dbkgroup.org/knownles/mQAP/>. From the approximation sets found by the three algorithms for each 20 and 30 location instances, the set containing only non-dominated solutions was computed and used as the reference set.

In addition to GD, performance assessment was also undertaken using PISA and the guidelines from [35] and [36]. Consider for example the comparison between GISMOO and PMS<sup>MO</sup> on a problem. First, the bounds of approximation sets of both algorithms were calculated so that the approximation sets could be normalized to the interval [1, 2]. After that, a dominance rank was calculated for each of the 60 approximation sets by simply counting the number of approximation sets that are better than the observed one. The Mann-Whitney rank sum test was used to discover if there are significant differences between the dominance ranks of the two algorithms.

## Results and discussion

Table 2 presents the average GD values obtained by each algorithm for the 22 mQAP instances. The first column of each table indicates the name of the problem. In this column a “\*” right after the name of the problem denotes the problems on which the GD was calculated using true Pareto optimal solutions, while “†” indicates that we used an approximation set to calculate the GD values. The following columns respectively show the average results over 30 runs for each algorithm. With regard to the average best results obtained, they are indicated by a shaded area.

Table 2 shows that GISMOO globally outperforms the other algorithms. Indeed, GISMOO’s GD metric is better than that of the other two algorithms in every one of the 22 tested instances.

| Problem        | Algorithm         |         |         |

Table 4: Outcomes of the Mann-Whitney rank sum test on dominance ranking for GISMOO and PMS<sup>MO</sup>

The Mann-Whitney rank sum test results also show that GISMOO globally outperforms the other two genetic algorithms. Indeed, GISMOO is never worse than NSGAI or PMS<sup>MO</sup> in any of the 22 mQAP instances. In fact, GISMOO is significantly better than NSGAI and PMS<sup>MO</sup> on all the instances. These results confirm the results obtained with the GD metric.

Beside the GD and Mann-Whitney rank sum test results, Fig. 1 and 2 graphically represent the solution sets found by GISMOO, NSGAI and PMS<sup>MO</sup> on a typical run using respectively two ten location problems: KC10-2fl-1uni and KC10-2fl-1rl. The KC10-2fl-1uni is a uniform instance while KC10-2fl-1rl is a real-like instance. In these two particular examples, we notice that GISMOO globally outperforms NSGAI and PMS<sup>MO</sup>. Indeed, in both cases the curves proposed by GISMOO dominated and are more extended than those of NSGAI and PMS<sup>MO</sup>. We also notice that for these two problems the approximation sets found by GISMOO are very close to the true Pareto optimal solution. In fact, for the problem KC10-2fl-1uni all the solutions found by GISMOO are also in the Pareto. These graphs confirm the results of the GD metric and the ability of our approach to find diversified solutions and to efficiently explore the solution space.

Figure 1: Non-dominated sets of a typical run of GISMOO, NSGAI and PMS<sup>MO</sup>

Figure 2: Non-dominated sets of a typical run of GISMOO, NSGAII and PMSMO on the KC10-2fl-1rl problem

## Conclusion

In this paper, we compared our GISMOO algorithm with two well known multiobjective algorithms (NSGAII, PMSMO) on twenty-two state-of-the-art benchmark mQAP problems. The biggest difference between GISMOO and other two algorithms lies in the environmental selection and the way in which the immune metaphor is used in a Pareto GA to identify and emphasize the solutions located in less crowded regions found during the iteration process of the algorithm. The preliminary experimental results obtained on the benchmark problems considered here have shown that our approach is efficient: on every problem, GISMOO outperformed the other algorithms with regard to the quality indicators used here. These results confirm those obtained in [21] and [2] respectively for other combinatorial and continuous optimization problems.

On the basis of these results we suggest that GISMOO is an efficient tool to solve the mQAP problem. In future work, we will seek to extend the numerical experiments to other performance metrics. We will also seek to extend the application field of GISMOO to other multiobjective problems in industry and elsewhere.

## Abstract

In this paper we study the performance of different evolutionary strategies based on explicit averaging. On a previous study, (Costa et al., 2012) proposed a probabilistic fitness function for an agent model based on neural networks and genetic algorithms employed to investigate the behaviour of rats in an elevated plus-maze (EPM). Differently from other computational models, the virtual rat proposed in (Costa et al., 2012) is not built based on experimental data comparisons with real rats, but, instead, is based on a behavioural model exploring the conflict between fear and anxiety. Despite the good results of the proposed agent, the effects of the uncertain fitness functions in the evolutionary learning process were not studied in the previous study. In our experiments we found significant differences in the performance of the genetic algorithm when the fitness of the individuals is sampled different times thus enabling us to define the best strategy for the studied problem.

Genetic algorithm, Uncertainty, Explicit averaging fitness, Elevated plus-maze, Rat

## Introduction

Uncertainty has been widely studied in different areas, like politics (Cioffi-Revilla, 1998; Carmignani, 2003), economics (Naceur Jabnoun and Yusuf, 2003; Pindyck, 2007; Baker et al., 2013), movies (Miller and Shamsie, 1999; Vany, 2004; Gil, 2008), sports (Jennet, 1984; Peel and Dennis, 1992; Knowles et al., 1992; Forrest and Simmons, 2002; Buraimo and Simmons, 2008), criminology (Lattimore and Witte, 1986; Goulas and Zervoyianni, 2013) and sociology (Marris, 1996). By reviewing the uncertainty literature, we find many concepts for this word. Early studies claim that uncertainty is product of unpredictability (Cyert and March, 1963) or environmental turbulence (Emery and Trist., 1965). In (Lawrence and Lorsch, 1967), uncertainty is described as the lack of knowledge in the decision making process and similarly, in (Duncan, 1972), uncertainty is the absence of information for decision making. Uncertainty is also faced as result of the complexity of influential variables (Galbraith, 1973).

Working with evolutionary computation, there are various kinds of uncertainties involved. According to (Jin and

Branke, 2005), these uncertainties may be classified into four groups:

1. the fitness function is subject to noise, which also may be comprehend as a problem of a partially observable environment;
2. the variables and/or the environmental parameters may change after simulation;
3. the fitness function is an approximation, which may cause errors;
4. the optimum of the problem is dynamic, so the optimizer has to seek the optimum continuously.

(Campi and Calafiore, 2004) adds another class to this list:

5. the optimization is based on sampling finite, small, number of instances (*scenarios*), normally because of the cost of obtaining each instance.

One of the classes of uncertainty problems that has been most studied is related to problems where the fitness function is subject to noise (Fitzpatrick and Grefenstette, 1988; Rattray and Shapiro, 1996; Sondahl and Stonedahl, 2010). Many of the solutions adopted to this class of problems investigate the influence of different selection schemes (Miller and Goldberg, 1996; Sano, 2002; Goschin et al., 2011) in the performance of the evolutionary algorithms. The problem studied here belongs to the first class of uncertain problems.

Uncertainty is also one of the greatest difficulties during decision making processes. The process of decision in rats navigating in mazes is widely investigated in animal behavioural studies (Salum et al., 2003; Walf and Frye, 2007). One of the mazes extensively used for this purpose is the elevated plus-maze (EPM). The EPM is an elevated plus-shaped maze composed of two opposed open arms and two opposed enclosed arms. The experiments using EPM are mostly derived from studies realized by Montgomery, in 1955, for the investigation of the conflict between fear and anxiety in rats during their exposition to a new environment (Montgomery, 1955). The conflict in the animal is

caused by sensations of curiosity and fear occurring simultaneously and understood as defence mechanisms (Graeff, 1990). Most of the studies of rats in the EPM are based on the results of Montgomery (Montgomery, 1955), which show that rats spend more time in the enclosed arms of the maze than in the open arms.

In the last years, some researches proposed computational models to simulate the rats behavior in the EPM (Salum et al., 2000; Giddings, 2002; Miranda et al., 2009; Shimo et al., 2010; Costa et al., 2012). In (Salum et al., 2000), artificial neural networks (ANNs), trained by competitive learning, control a virtual rat in a virtual EPM. The inputs of the ANN are: need for exploration, aversion repulsive stimuli, and spontaneous motor activity. In the paper, the authors also studied a completely open and a completely closed maze. (Miranda et al., 2009) proposes a very similar model. (Giddings, 2002) implements a computational model based on the fact that the rat generally remains in the direction that it already is. The probabilities of following the previous direction, or moving to other direction, are defined a priori for different parts of the maze.

Other approach is used in (Shimo et al., 2010; Costa et al., 2012), in which the virtual agent is obtained from a optimisation process. In this case, the agent is a mobile robot controlled by an ANN. The weights of the ANN are defined by a genetic algorithm (GA), which uses a fitness function based on the comparison of the trajectories of the individuals in a replica of the EPM and the trajectories of real rats in an EPM.

According to the authors' knowledge, (Costa et al., 2012) proposed the first model in which the virtual agent is obtained independently from experimental data obtained with real rats. In the same way of the model proposed in (Shimo et al., 2010; Costa et al., 2012), the computational agent (a virtual robot) is represented by an artificial neural network, whose weights are evolved by a genetic algorithm. The outputs of the ANN determine the next action of the virtual robot. The main contribution of (Costa et al., 2012) is a probabilistic fitness function that is not dependent of experimental data obtained with experiments using real rats, but is based on the relation of fear and anxiety related by Montgomery. The results of the experiments with real rats are employed only in the validation of the model. The experimental results showed that the virtual model was capable of reproducing the rats behaviour, when some parameters of the trajectories like number of entrances and time spent in each arm are considered. However, the effects of the uncertainty inherent to the fitness function were not studied on our previous study (Costa et al., 2012). The problem by using a probabilistic function, is that the comparison of candidate solutions can be unfair, causing bias in the selection of the individuals, and affecting the evolutionary process.

As mentioned in (Jin and Branke, 2005), one of the classes of uncertainty in evolutionary optimisation occurs

when the fitness function is noisy, and there are many types of strategies to deal with that uncertainty. One of them is explicit averaging, where the fitness of an individual is sampled a number of times. In this paper, we test different evolutionary strategies based on explicit averaging for the model proposed in (Costa et al., 2012), with the intention of reducing the effects of the uncertainty in the fitness function employed by the virtual robot. One problem with explicit averaging is the additional computational costs for the optimisation algorithm. This is particularly true for problems where the evaluation process is costly, like in robots. If the evaluation is costly, an option is to use a less accurate fitness function and another option is to calculate the average based on fewer independent individual evaluations (Sondahl and Stonedahl, 2010). However, this is not the case of our problem, as the fitness evaluation can be split in two parts: one to obtain the trajectory of the agent, which is costly, and another to compute the fitness based on this trajectory. Since the last one is not costly, we are able to make many independent evaluations to calculate the mean fitness for each individual without significantly changing the time required to evaluate an individual.

In next section we explain the computational methods for the virtual rat and the four strategies studied in this paper to deal with uncertainty. In Section III, we present experiments comparing the fitness and the time spent in the enclosed and open arms for the virtual rats obtained with these strategies. Conclusions and future directions are presented in Section IV.

## Methodology

In this paper, a computational agent (virtual robot) is employed to simulate the behaviour of a rat in the EPM. The virtual robot is controlled by a recurrent multilayer perceptron (Elman's network) with ten inputs (six sensors and four recurrent signals from the hidden layer), four neurons in the hidden layer, and four neurons in the output layer. The recurrence is important because it allows that previous inputs be stored in the internal neurons, acting like a memory. The sensors are placed around the robot in order to detect the walls of the EPM. The outputs of the ANN indicate the next robot's action (stay, turn left, turn right or go forward to the next position).

A genetic algorithm optimises the weights of the artificial neural network. This way, each individual of the GA corresponds to a chromosome composed by an array of integers, representing a possible solution in the fitness landscape. The initial population is randomly chosen.

The same virtual EPM proposed in (Salum et al., 2000) is employed in our work. Each arm of the plus-maze is divided in five positions plus the central position that links the four arms of the EPM, totalling 21 positions. The agent (rat or virtual robot) is evaluated by its navigation in this virtual EPM during a period of time corresponding to 5 minutes for

the real rat, or 300 time steps for the virtual rat.

The fitness function, proposed in (Costa et al., 2012) and employed here, is based on the conflict of fear and anxiety model (Montgomery, 1955). Two terms compose the fitness function: one for reward and other for punishment. The reward represents the curiosity of the rat in exploring not recently visited positions of the maze, while the punishment represents the exposure to damage. This last term is probabilistic, i.e., the same trajectory of the agent in the EPM can generate different values for this term. The fitness of individual  $\mathbf{x}$  is computed based on the trajectory of the agent controlled by the ANN with weights given by the chromosome of the individual in the virtual EPM. In this way, after selection and reproduction, each individual of the GA generates a trajectory in the virtual EPM and this trajectory generates the fitness of the individual according to the following function:

$$f(\mathbf{x}) = \sum_{t=1}^n r(\mathbf{x}, p_t) + s(\mathbf{x}, p_t) \cdot \beta, \quad (1)$$

where  $p_t$  is the position of the virtual rat at time step  $t$ . The term of reward ( $r(\mathbf{x}, p_t)$ ) may increase the fitness of the individual, following the rule:

$$r(\mathbf{x}, p_t) = \begin{cases} 1, & \text{if } p_t \text{ was not visited for the agent} \\ & \text{in the last } \gamma \text{ time steps} \\ 0, & \text{otherwise,} \end{cases} \quad (2)$$

where  $\gamma$  is a parameter of the model that is related to the memory of the virtual rat.

On the other hand, the punishment ( $s(x, p_t)$  in Eq. 1) represents the exposure to the damage and decreases the fitness of the individual. It is known that the rat avoids the damage by spending more time in the enclosed arms, i.e., the level of damage is different for different positions of the maze. This way, the punishment is given by  $s(\mathbf{x}, p_t) \cdot \beta$  in Eq.(1), in which  $\beta$  is the weight of the punishment and

$$s(\mathbf{x}, p_t) = \begin{cases} -1, & \text{if } z_i < \alpha(p_t) \\ 0, & \text{otherwise,} \end{cases} \quad (3)$$

where  $z$  is a random number, and  $\alpha(p_t)$  is the level of damage of the position  $p_t$  occupied in the time step  $t$ :

$$\alpha(p_t) = \begin{cases} \alpha_o \in [0, 1], & \text{if } p_t \text{ is an open arm} \\ \alpha_e \in [0, 1], & \text{if } p_t \text{ is an enclosed arm} \\ \alpha_c \in [0, 1], & \text{otherwise.} \end{cases} \quad (4)$$

The more the rat is exposed to danger, the higher is the chance of it being punished, which means that the punishment is probabilistic. That is, the fitness function is noisy and may be compared to a robot walking around an uncertain environment. The strategies described in the next section were studied to deal with this kind of uncertainty.

## Evaluation

As mentioned previously, we study four different evolutionary strategies for the GA. The individual's selection and fitness depend on the employed strategy. In the experiments, for each strategy, we calculate the mean over 30 executions of the GA and the population size is constant throughout the simulation (500 individuals).

The fitness of the individual is calculated based on the trajectory of the corresponding agent. After navigating in the EPM, the corresponding trajectory of the virtual robot is recorded. Then, the fitness based on this trajectory is sampled  $n$  times using Eq. (1) and the individual's fitness is given by the mean fitness of these  $n$  independent results. That is, the trajectory of a individual, which is the more costly part of the evaluation process, is performed only once. The mean of various fitness computations are calculated because of the uncertainties of the fitness function, as seen in the last section. The evaluation process may be seen in Figure 1. It is important to highlight that, in (Costa et al., 2012), the fitness is sampled only one time, i.e.,  $n = 1$ .

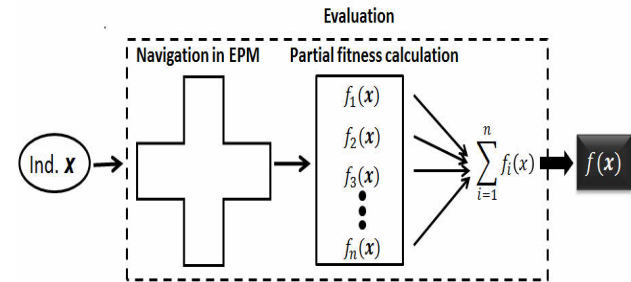

Figure 1: Process of individual evaluation. First, the individual navigates in a simulated five-minute test. The fitness based on this trajectory is then sampled  $n$  times. The resultant individual fitness is the mean of these independent fitness calculated.

## Strategies

The four strategies studied here are presented below.

**Strategy 1** The individuals are selected by elitism and tournament. By elitism, the two best individuals of the population are selected to the next population. In tournament selection, the best of two random individuals is selected, with probability 0.75, and the selected individual is then submitted to the reproduction operators. The tournament occurs until the population is completed. One-point crossover (with rate of 0.6) and mutation with uniform distribution (with rate of 0.05) are employed. The population evolves during 500 or 1500 generations (depending on the experiment), concluding an execution of the GA. Then (**after GA simulation**), the best individual of each of the 30 executions is evaluated with  $n$  partial fitness calculations and the mean fitness

represent the fitness of these individuals. It is important to observe that during the GA evaluation, each individual is sampled with  $n = 1$  on each generation of the evolutionary process.

**Strategy 2** This strategy is similar to Strategy 1. The difference is that each individual of the population is evaluated based on  $n$  samples of the fitness function. Then, at the end of each execution, the best individual is selected and it is not evaluated again.

**Strategy 3** Strategy 3 is the same of Strategy 1, except that the only type of selection is tournament. There is not elitism.

**Strategy 4** In this strategy we do the same of Strategy 2, but without elitism.

## Results

In previous experiments, we have tested several sets of parameters and the selected for the virtual robot simulations are:  $\gamma(p_t) = 3$ ,  $\beta = 5$ ,  $\alpha_o = 0.015$ ,  $\alpha_e = 0.012$  and  $\alpha_c = 0.011$ , which are used in all simulations presented here.

Table 1 exhibits the mean fitness obtained with the Strategies 1, 2, 3 and 4, based on 30 executions of 500 generations each one. In the evaluation, the fitness is computed 10 times for the best individuals of each run. By the table, it is clear that the best results are achieved with Strategy 1, in which the fitness exhibited corresponds to the mean of the best individuals of 30 executions of the GA evaluated after simulations. Strategies without elitism (Strategy 3 and 4) are worse than their similar with elitism. It shows that elitism is important to the model.

| Statistic | Strategy 1 | Strategy 2 | Strategy 3 | Strategy 4 |
|-----------|------------|------------|------------|------------|
| Mean      | -10.94     | -15.60     | -11.29     | -16.08     |
| Sd        | 3.98       | 1.31       | 4.52       | 0.01       |
| Min       | -18.84     | -16.12     | -22.48     | -16.11     |
| Median    | -11.15     | -16.072    | -11.60     | -16.08     |
| Max       | -2.88      | -11.41     | -1.98      | -16.06     |

Table 1: Simulated results of the fitness in 30 runs of 500 generations for Strategies 1, 2, 3 and 4, with  $n = 10$ .

To clarify how close our results are to the experiments with real rats, Figure 2 contains mean and standard deviation of the time spent in each arm and central position obtained by experiments with real and virtual robots. The experimental results with real rats are based on the trajectory of 47 rodents (Costa et al., 2012).

Virtual robots spend similar proportions of time in each arm of the EPM in relation to real rats, remaining substantially longer in the enclosed arms. The qualities of the strate-

Figure 2: Mean and standard deviation of the time spent in enclosed and open arms and in the central position of the EPM for real rats and for virtual robots with the four strategies studied.

gies are in agreement with their respective fitness presented in Table 1.

Since we conclude that elitism is fundamental to keep best individuals in the population, the next results are all obtained with elitism. Our intention is to better understand the model and the influence of Strategies 1 and 2. For this purpose, we found the best individuals of 30 executions of both 500 and 1500 generations with Strategy 3 for  $n = 1$ ,  $n = 10$  and  $n = 100$ . Then, we evaluated them again after the runs, like is done in Strategy 1, calculating 100 partial fitness for each one of best individuals obtained in the 30 runs. We calculated the mean, standard deviation, median, maximum and minimum of the 30 fitness. The result is shown in Table 2.

| Statistic | 1ft 500ger | 1ft 1500ger | 10ft 500ger | 10ft 1500ger | 100ft 500ger | 100ft 1500ger |
|-----------|------------|-------------|-------------|--------------|--------------|---------------|
| Mean      | -9.79      | -9.46       | -11.50      | -7.97        | -0.92        | 1.60          |
| Sd        | 3.16       | 3.77        | 8.04        | 6.08         | 9.76         | 4.50          |
| Min       | -17.91     | -15.75      | -22.03      | -17.03       | -21.21       | -6.45         |
| Median    | -9.98      | -9.49       | -8.11       | -7.37        | 3.12         | 3.13          |
| Max       | 3.57       | 3.31        | 2.70        | -7.37        | 6.95         | 9.09          |

Table 2: Mean, standard deviation, minimum, median and maximum for the best individual of 30 executions of 500 and 1500 generations of Strategy 2 with  $n = 1$ ,  $n = 10$  and  $n = 100$ , associated with Strategy 1 with  $n = 100$ .

From Table 2, it is clear that increasing from 500 to 1,500 the number of generations in the GA, the quality of the re-

sults is improved in any studied situation. It also may be seen that increasing the number of samples of the fitness function is beneficial to the model. To improve the comprehension of what is happening, we analysed histograms of fitness coming from Strategy 2 with  $n = 1$  and  $n = 100$ . The best individual of the 30 executions is evaluated again with 1000 samples (partial fitness). These samples are in the histograms of Fig. 3, which also exposes the original fitness for  $n = 1$  and  $n = 100$ , i.e., the fitness of the best individual of the simulations whose trajectory was selected to be evaluated a thousand times ( $f_1$  and  $f_{100}$ , for the case with  $n = 1$  and  $n = 100$  respectively). We observe that  $f_{100}$  is a little higher than the average of 1,000 evaluations, while  $f_1$  is much higher, close to the maximum fitness obtained in the 1,000 evaluations. The value for  $f_1$  is high because the individual's fitness obtained with the calculation of only one sample is more susceptible to randomness. Since various individuals in the population have similar genome, that one with the maximum fitness is selected with higher probability, causing the bias in the histogram. On the other hand,  $f_{100}$  is the mean of a thousand samples, which ensures that the fitness will be near the mean fitness allowed for the trajectory evaluated for the various individuals with the same genome in the population. As this individual is selected with higher probability, it is progressively better along the executions. But this process occurs in a very slow way, compared to the case for  $f_1$ .

The Figure 3 enables to observe how noisy is the fitness function studied. One can observe, in the histograms, regions without samples. This occurs because the punishment weight is equal to 5.8 ( $\beta = 5.8$ ) in the runs, whereas the reward is equal to 1. So, there are values that are not covered by the possible combinations of rewards and punishments in Eq. 1 (one can remember that the reward is deterministic while the the punishment is probabilistic for a given trajectory).

Figure 4 shows the maximum, mean and minimum fitness of each generation for the best of 30 executions of the GA in simulations of Strategy 2 with  $n = 1$ ,  $n = 10$  and  $n = 100$ . As it was already presented, increasing the number of samples improves the fitness achieved by the optimisation process. The figure demonstrate that there is a jump in fitness around the 500th generation in strategy with  $n = 100$ , revealing that the virtual robot learns a new skill at this point of evolution. It is interesting to observe that it only happens when 100 samples of the fitness are considered. By analysing the amount of punishments and rewards received by the best individual of each generation, we can note that this jump is due to fact that the virtual robot have learned how to be more rewarded in his trajectory.

## Conclusions

The results show that explicit averaging is important to the studied problem, as our fitness function is probabilistic. The

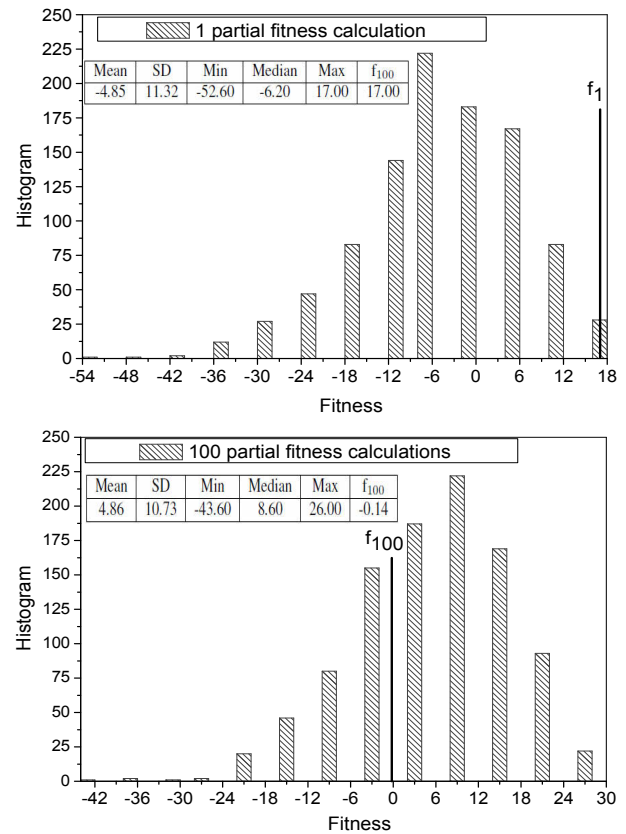

Figure 3: Histogram of 1,000 samples for the best individual obtained in 30 runs for Strategy 2 with  $n = 1$  (up) and  $n = 100$  (bottom). The tables show the mean, standard deviation, minimum, median, maximum and the original fitness.

Figure 4: The up three lines are the maximum fitness; the central three lines correspond to the mean fitness; and the bottom lines are the minimum fitness of each generation for a run of Strategy 2 with  $n = 1$ ,  $n = 10$  and  $n = 100$ .

fitness function studied is very noisy, influenced by the reward and punishment weight values in the fitness function.

It is relevant to highlight that the navigation in the EPM is the most costly part of the evaluation process. It takes a robot a long time to perform its trajectory in a EPM's replica (as it did in (Shimo et al., 2010)). Hence, it is possible and fair to calculate a high number of samples of the fitness function for each individual evaluation.

Among the four strategies studied for the problem of the rat navigating in an elevated plus-maze, the most effective one is to evaluate the best individual with 100 samples of the fitness functions during the optimisation process. This is caused by the fact the explicit averaging smooths the effect of randomness in the fitness function. We also noticed that selection by elitism plays an important role in the evolution of the evolutionary robots for the problem studied here.

As a future work, we intend to study the influence performed by the ANN and each neuron from the hidden layer. Moreover, we intend to test the methods also in real robots.

# Speciation Dynamics: Generating Selective Pressure Towards Diversity

Heiko Hamann

Department of Computer Science, University of Paderborn, Paderborn, Germany  
heiko.hamann@uni-paderborn.de

## Abstract

Recent approaches in evolutionary robotics (ER) propose to generate behavioral diversity in order to evolve desired behaviors more easily. These approaches require the definition of a behavioral distance which often includes task-specific features and hence a priori knowledge. Alternative methods, that do not explicitly force selective pressure towards diversity (SPTD) but still generate it, are known from the field of artificial life such as artificial ecologies (AE). In this study, we investigate how SPTD is generated without task-specific behavioral features or other forms of a priori knowledge and detect how methods of generating SPTD can be transferred from the domain of AE to ER. A promising finding is that in both types of systems, in systems from ER that generate behavioral diversity and also in the investigated speciation model, selective pressure is generated towards unpopulated regions of search space. We conclude by hypothesizing how knowledge about self-organizing SPTD in AE could be transferred to the domain of ER.

## Introduction

Methods of evolutionary computation have been successful as optimization technique for many years. Also the optimization of behaviors, which can justifiably be called ‘generation of behaviors’, in the field of ER (Nolfi and Floreano, 2000) has proven to be effective. However, the next step in this research towards more complex behaviors and tasks seems to be particularly difficult. Such a complex task could involve, for example, several successive sub-tasks whereas learned earlier sub-tasks have no utility before later sub-tasks are learned as well. The relative simplicity of investigated tasks in ER, especially when compared to natural systems, is, for example, discussed by Nelson et al. (2009).

Evolving robot behaviors becomes even more challenging if the necessary a priori knowledge is minimized which is necessary to achieve generally applicable approaches. Notably this concerns the fitness function and how elaborated it is. Nelson et al. (Nelson et al., 2009) define several fitness function classes such as the

behavioral fitness functions which incorporate a lot of a priori knowledge (fitness function ‘selects for behavioral features of a presupposed solution to a given task’, i.e. *how* the task is accomplished) and the aggregate fitness functions which incorporate a very low degree of a priori knowledge (fitness function measures *what* the robot has accomplished and not *how* it was accomplished). Behavioral fitness functions are applied in ER because otherwise behaviors of certain complexities cannot be evolved with a reasonable commitment of resources.

An option is to increase the diversity in the population, e.g. by fitness sharing, see (Sareni and Krähenbühl, 1998). However, these methods include the measurement of a distance between genotypes which is computationally intractable for common encodings in ER, such as artificial neural networks (ANN) (Mouret and Doncieux, 2012). Instead promising recent results suggest to increase the behavioral diversity during the search or within the current population and measure the distances between behaviors which can be done efficiently. Examples are novelty search (Lehman and Stanley, 2011) and the approach by Mouret and Doncieux (Mouret and Doncieux, 2009, 2012). Novelty search (Lehman and Stanley, 2011) operates without an actual objective function. Instead selective pressure is generated towards behaviors that have not been seen before in the evolutionary run. A desired behavior is that that maximizes the behavioral distance to all known behaviors. For illustration and later use this is shown schematically in Fig. 1a. The circles represent behaviors that were found during the evolutionary run (graded colors represent different generations) and their position in search space. Behaviors that are close to known behaviors are undesirable which is represented by low values of the fitness function  $F$  around circles. Consequently selective pressure towards unpopulated regions in search space is generated which is represented accordingly by steep, upward slopes around circles. Multi-objective behavior diversity (MOBD, Mouret and Doncieux, 2009) includes the

Figure 1: Schematic representation of the fitness functions generated by novelty search (Lehman and Stanley, 2011) and MOBD (Mouret and Doncieux, 2009); circles represent known behaviors, selective pressure is towards bigger values of  $F$ .

behavioral distance only as a component in the multi-objective fitness function. In contrast to novelty search it only accounts for the behaviors in the current population. This is sketched in Fig. 1b.

For approaches of behavioral diversity a distance between behaviors needs to be defined, which typically will be task-specific. Hence, this is a process similar to defining an appropriate fitness function for a given task in standard ER. It is argued that even naive behavioral distance definitions can improve the evolutionary process, such as definitions based on the final position of the robot or of movable objects at the end of the evaluation (Mouret and Doncieux, 2009; Lehman and Stanley, 2008). However, if we follow the analogy to fitness functions, it seems likely that for more complex tasks the measure of behavioral distance will also need to be more complex. This factual connection gets even more plausible if we reconsider the above mentioned comment by Nelson et al. (2009) about behavioral fitness functions (which select for behavioral features). In the design of the behavioral distance measure not only *what* is accomplished is relevant but also *how* it is accomplished. In a simple exploration task this is not really apparent, if the behavioral distance is defined on the robot's final position (Mouret and Doncieux, 2009), but it addresses at least the order of how the maze is explored. In a more complex task such as the locomotion of a biped robot (Lehman and Stanley, 2011) it gets more apparent

as the behavioral distance is defined by the trajectory of the center of mass (how) instead of just the total offset (what). Hence we state the hypothesis that also methods based on behavioral distances will run into similar problems as seen in fitness function design such as having to define 'task-specific hand-formulated functions that contain various types of selection metrics' (Nelson et al., 2009) and consequently having to involve a high degree of a priori knowledge.

Based on our hypothesis we assume that neither genotypic distances nor behavioral distances are able to generate sustainable diversity in ER. What could be candidate solutions? Natural evolution represents a perfect standard for the generation of diversity. Particularly we are interested in evolutionary radiation which is an increase in taxonomic diversity. A typical example of a radiation is the Cambrian explosion. It generated a diversity that is comprehensible when looking at the corresponding phylogenetic tree which gets literally bushy within a comparatively short period of time. Each branching corresponds to an event of speciation. Hence, to understand diversity we want to understand speciation and the underlying process that generates SPTD. Our objectives are 1) to detect how SPTD is generated in a self-organizing system (e.g., speciation) and 2) how to transfer this knowledge to ER.

Next we summarize the knowledge on how speciation operates. Coyne and Orr (2004) ask: 'Why are there species?' and they comment: 'we regard it as one of the most important unanswered questions in evolutionary biology'. Accordingly they do not answer but only discuss the question. They point to Maynard Smith and Szathmary (1998) who consider three explanations. One, species are discrete 'stable states' formed by a self-organizing system. However, this option lacks a mechanism that would explain the origin of species. Two, species fill discrete ecological niches. Third, reproductive isolation is an inevitable result of evolutionary divergence. The latter two are dependent on reproductive isolation and are not mutually exclusive (Coyne and Orr, 2004). A conclusive concept that connects both is that of 'adaptive peaks' (Dobzhansky, 1951). Species are adaptive peaks that are separated by 'adaptive valleys' which are genotypes that are unfit for survival. Whether these adaptive valleys are due to ecological or environmental effects is kept open. Another aspect is whether asexual or sexual reproduction is considered. While in the case of asexual reproduction ecological niches seem to be indispensable to create a reproductive barrier, in the case of sexual reproduction the reproductive barrier might be generated without explicit ecological niches especially because sexual selection could be effective. To summarize we note that evolutionary radiation and speciation are yet difficult to understand as

also pointed out by Venditti et al. (2010): ‘Attempts to understand species-radiations [...] should look to the size of the catalogue of potential causes of speciation shared by a group of closely related organisms rather than to how those causes combine.’ The conclusion concerning inspirations for new methods to generate diversity in artificial evolution, especially ER, regrettably has to stay inconclusive for now due to the limited knowledge about the natural system itself. However, it is the starting point of the following investigations.

Instead of detecting methods to generate speciation, what are prerequisites for evolutionary radiation, that is, for active speciation? A prerequisite could be the existence of a complex environment that favors the formation of adaptive peaks and that initiates specialization in the organisms. Another prerequisite could be the existence of an ecology which creates complexity in the interaction of different organisms and species. The suitability of providing a complex environment within applications of ER is limited, notably if a complex environment is not part of the desired task. On the contrary, a considerable amount of research on the creation of AE in order to evolve behaviors has been reported. For example, the minimal ecology, that of just two species, is investigated in studies of coevolution (Floreano and Nolfi, 1997) and AE, possibly with many species, are popular in the field of artificial life (Ray, 1991). The studies of coevolution have an emphasis on the actually evolved behaviors combined with considerations about their utility and complexity. It turns out that ‘the co-evolutionary process tends to fail into dynamical attractors in which the same solutions are adopted by both populations over and over’ (Nolfi and Floreano, 1998b). In AE studies the actual behaviors are of less interest, instead the evolutionary process as a whole is usually investigated in more detail. In addition it is also unclear how these AE would have to be designed to generate desired behaviors for a given task. Common to both is their high sensitivity to parameters and the challenge of creating actively progressing evolutionary processes. However, they are interesting examples of how SPTD is generated in a self-organizing process without incorporating a priori knowledge about how a certain behavior is accomplished. Summing up, the prerequisite to generate diversity is a minimum of complexity that provokes the emergence of adaptive peaks. The trigger could be ecological or environmental features but also effects of sexual selection. The goal of this study is 1) to detect and measure SPTD which is generated by a self-organizing process in AE, and 2) to determine how methods from the domain of AE could be transferred to ER. To the knowledge of the author, published studies on behavioral diversity tend to focus either on self-organizing diversity without aiming for the solution of

a given task (e.g., Ray (1991)) or on explicitly imposed SPTD while searching for the solution of a particular task (e.g., Lehman and Stanley (2011)). In the following we investigate a speciation model of Woehrer et al. (2012) and an extension to it in order to investigate how SPTD is generated in this self-organizing system. The results are then compared to approaches that explicitly impose SPTD.

## A model of speciation

One distinguishes several types of speciation, such as allopatric speciation and sympatric speciation. Previously it was thought that speciation happens mostly allopatrically, that is, by spatial separation of populations which then develop reproductive isolation. More recent results (Coyne and Orr, 2004) support that sympatric speciation, which is speciation within the same geographic region, might be more common than expected. Here, sympatric speciation is of more interest because it is a self-organizing, evolutionary process while allopatric speciation occurs due to external forces (arguably except for migration). In terms of the application of speciation to increase the behavioral diversity in ER, sympatric speciation is preferred as it does not need a priori knowledge while allopatric speciation would need an implementation of a cause.

Woehrer et al. (2012) report an artificial life model of sympatric speciation based on sexual selection, in particular assortative mating which is a mating pattern where mating between individuals with similar geno-

types or phenotypes is more likely. The model is inspired by the natural system of finches on the Galápagos Islands. Although an island setting might let allopatric speciation appear as a good and exclusive explanation this does not seem to be the case on the Galápagos Islands (Woehrer et al., 2012). Woehrer et al. (2012) point to the specialty of the proposed system that combines natural selection and sexual selection acting on the same trait which is directly related to so-called ‘magic traits’ (Servedio et al., 2011). Here we reproduce their results, report an extension of the model, and perform additional measurements in simulations.

The artificial system models a bird population of dynamic size. A bird is modeled by age, beak size, energy level, and gender. To survive the birds have to forage (implemented as random search) for seeds. These are modeled by energy, location, uniformly distributed size, and distributed in discrete space of size 100 units  $\times$  100 units (see table 1 for used parameter settings). Selective pressure is imposed by the limited resource of seeds. Initially of the dry season a number of seeds is placed in the world which decreases consecutively over a period of 30 or 43 simulated days (depending on which setting is used) as the birds forage from it. The birds’ search for seeds is limited by their beak size  $s$  because they can only feed on seeds of size  $[s - 1, s + 1]$ . The search costs energy on each day and fed seeds add energy to the bird’s energy. If a bird runs out of energy during the dry season it dies. Those that survive may attempt to reproduce. Reproduction is based on sexual selection and assortative mating (with random mating no speciation was observed (Woehrer et al., 2012)). Females with beak size  $s_f$  select only mates with beak size  $s_m$  within the female’s beak size interval  $s_m \in [s_f - \Delta, s_f + \Delta]$  for assortative range fixed to  $\Delta = 0.5$ . The offspring has a beak size averaged over its parents plus Gaussian noise and random gender. For all remaining details please see (Woehrer et al., 2012) and table 1.

A typical run is shown in Fig. 2a which is a plot of all beak sizes that occur in the population over 375 generations. The resemblance to a phylogenetic tree is obvious. Also the drift of species, branching into two species, and the extinction of species can be noticed. Hence the model of Woehrer et al. (2012) is a simple model of self-organized speciation and can be used as an easy-to-handle analogy to the studies on behavioral diversity in ER. The interval of allowed beak sizes  $[1, 10]$  is the equivalence to the behavior space and a bird’s beak size would be the 1-d equivalence to the behavior defined by ANN. The extreme difference between high-dimensional ANN and the simplistic 1-d beak size interval is not a limiting factor of this analogy because the speciation model possesses the one qualitative feature that is relevant for this study, namely self-organized generation

of diversity. The assortative mating corresponds to allowing recombination only for ANN that share a ‘magic trait’ which is defined by sexual selection and could be a behavioral feature. In addition, this way the emergence of speciation relies crucially on a pre-defined parameter (assortative range  $\Delta$ ). In order to avoid such a pre-defined measure for the above mentioned reasons we can allow the evolutionary algorithm to vary features of sexual selection. The perfect solution would be to evolve the full process of sexual selection which is, however, beyond the scope of this paper. Instead we restrict the following investigations to the evolution of the allowed difference between females’ and males’ beak size defined by the assortative range  $\Delta$  in this particular case of assortative mating. While this solves the problem of having pre-defined parameters, this would still correspond to a pre-defined process of sexual selection. That way we are able to investigate whether the evolutionary process can self-organize towards a higher degree of diversity without being forced to do so by a parameter setting.

It turns out that the model is very sensitive to settings of the assortative range  $\Delta$  which is typical for such systems as pointed out above (Sec. ). If  $\Delta$  is set too low, species extend over a narrow interval of beak sizes, feed from a small set of seeds that they are able to eat, and become extinct often (data not shown). If  $\Delta$  is set too big, no speciation is observed because one big connected component of birds in ‘beak size space’ emerges. Still we proceed and allow the assortative range  $\Delta$  to be evolved. The extension of the above model is described in the following. The parameter  $\Delta$  that defines sexual selection by setting the beak size range is defined now as an individual bird property. It is passed on by an average over the parents plus Gaussian noise (see table 1 for parameters). Furthermore, we introduce an evolved parameter of each individual bird called ‘seed width’  $W$  to increase the attractiveness of being a specialist. In addition to the beak size it also determines the interval of seed sizes a bird is able to feed on ( $[s - W, s + W]$ , priority is with the more restrictive interval) and the energy of a seed is scaled by  $1/W^2$  (for  $W < 1$  a seed’s energy is increased quadratically in  $W$ ). The system shows also speciation without this additional feature of seed width  $W$  but the inclusion of seed width stimulates speciation (data not shown).

For the following presentation and analysis of our results we define a technical concept of species in this simple model. In order to do so we interpret the distribution of a population’s beak sizes as a graph whereas each bird’s beak size represents a node and two such nodes are connected to each other if they are within each others individual assortative range of sexual selection defined by  $\Delta$ . A species is defined by the graph-

Figure 2: Beak sizes  $s$  over generations  $t$  for fixed and evolved assortative mating; for parameters see Tab. 1; sub-figures b-d differ only in random initialization.

theoretic concept of connected components: a subset of nodes and for each pair of such nodes there is a path connecting both. With this definition we are able to implement an automatic classifier that determines where and how many species exist in a given configuration.

## Results

In the following we investigate whether speciation is observed, we investigate the distribution of beak sizes over time to find what is beneficial for speciation in this extended model, the distribution of branch lengths, and the dynamics of species. With this extended model we obtain for different random initializations results (for parameters see Tab. 1) that are characterized by three classes: showing speciation (see Fig. 2b), intermediate (see Fig. 2c), and not showing speciation (see Fig. 2d). Following our connected-component definition, species within limited beak-size intervals and clear separation are noticed in Fig. 2b. In Fig. 2c species are not clearly separated at all times. For example, at  $t \approx 600$  one species spans almost over the whole beak-size interval. In Fig. 2d, a single species covers the whole interval. Hence this system does not reliably self-organize towards diversity, at least for the tested parameters.

For the following investigations we classify occurrent

configurations. It turns out that four configurations are frequent: only species in the left part of the beak size interval ( $s < 4.5$ , called *left*, frequency: 3.24%), only species in the right part ( $s > 6.5$ , called *right*, frequency: 3.14%), species distributed over the whole interval (called *all-over*, frequency: 88.37%), and species in the two outer parts but not in the middle (called *symmetrical*, frequency: 5.24%). Concerning the evolved assortative range  $\Delta$ , the all-over configuration is distinguishable from the three other configurations. In Fig. 3a the distributions of all occurring assortative ranges over a number of evolutionary runs are compared. The mean for all-over configurations is 1.9 and bigger than those of the others (about 1.3). With bigger assortative range a species spans over big intervals more easily. Consequently big assortative ranges counter diversity in terms of speciation. The populations that spread over the whole interval are bigger than those showing diversity (mean of about 200 birds compared to about 100) because they exploit the energy provided by seeds fully. Consequently they are less prone to fluctuations and have a smaller risk of extinction. At the same time they make sure to exploit seeds of all sizes. Hence the low-diversity solution actually seems to be the evolutionary more robust approach which raises the question of how speciation could be stimulated additionally (an optional target of an investigation which is beyond this paper would be the tradeoff between a generalist's advantages and costs due to seed width  $W$ ). In turn it is possible to force the system into speciation by forcing bi- or multi-modal distributions of seed sizes (Woehrer et al., 2012). However, this is tweaking the environment which is not a good option for our application in ER.

Generally, populations with big assortative ranges seem to be more stable and there is also a tendency of spreading over the whole interval with increasing time. We are able to support this claim by investigating the distribution of branch lengths in the phylogenetic trees. The branch length is the time period between split-ups of species and/or their extinction. Based on an automatic check for connected components, species and the corresponding branch lengths are determined in the implementation of the model. The distribution of branch lengths based on independent evolutionary runs ( $4.4 \times 10^5$  samples) is shown in Fig. 3b (squares). In the analysis of this data we follow Venditti et al. (Venditti et al., 2010) who discuss and interpret different branch length distributions of phylogenetic trees. While they apply their methods to natural systems we found that they can also be applied to this artificial system. The best fit we found is the Weibull distribution ( $ca/bx^{(a-1)} \exp(-(x/b)^a)$ ,  $a = 0.32$ ,  $b = 0.065$ ,  $c = 29 \times 10^3$ ) which Venditti et al. (2010) interpret in the following way: “the Weibull density can accommodate

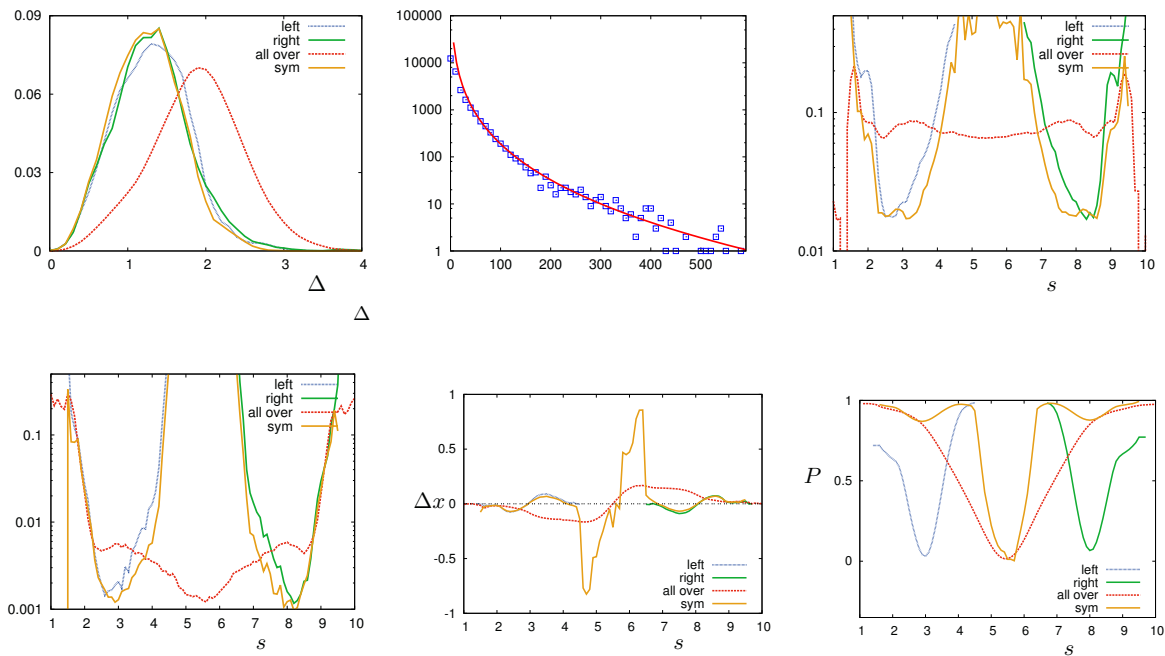

Figure 3: Distribution of the assortative range  $\Delta$  for different configurations and the distribution of branch lengths in the phylogenetic tree with fitted Weibull distribution; birth and death rate of species over beak size for different configurations; averaged movement of species and implied potentials over beak size for different configurations.

the probability of speciation changing according to the amount of divergence from the ancestral species. This model will fit the data if, for example, species are either more or less likely to speciate the older they get.” This supports our finding that old species tend to speciate less as they tend to span the whole interval.

Despite these shortcomings in the sustainability of the evolution of species we are able to investigate the dynamics of speciation in this system. Our aim is to detect and measure how SPTD is generated without explicitly forcing it. The evolution of species in space and time based on the above connected-component definition can be interpreted as a discrete birth–death process combined with drifting motion. For the above defined four classes of configurations the birth and death rate depending on the beak size were measured, see Fig. 3c and d (qualitative, no errors shown). The birth rate is bigger by about an order of magnitude because in our implementation the merger of species was not classified as death; only actual extinction was classified as death. Interestingly the birth rate for the all-over configuration is almost homogeneous while the other configurations have a dip at  $s \approx 3$  and  $s \approx 8$ . This is most likely because species in the all-over configuration are in average almost evenly distributed while in the other configurations species are more likely to be positioned at  $s \approx 3$  and/or  $s \approx 8$ . Once this ‘niche’ is covered, a birth at

the same position is not possible. The death rates of all configurations have peaks at the bounds which is explained by the smaller number of available seeds once birds cover also seed sizes that do not occur ( $< 1$  or  $> 10$ ). Interestingly beak sizes keeping a distance to the bounds support survival for all configurations.

In the following we want to measure the dynamics of species, that is, the average movement of species in beak size space in certain configurations. A measurement of how the species drift for the four configurations is shown in Fig. 3e.  $\Delta x$  gives the average displacement of a species from one to the next generation for  $1.9 \times 10^7$  samples. Positive values  $\Delta x > 0$  describe the drift of a species towards bigger beak sizes and negative values  $\Delta x < 0$  describe drift towards smaller beak sizes. For the configurations *left*, *right*, and *all-over* the average motion of species indicates spreading and species keep moving towards the bounds even when already approaching them which means they move into regions of high death rates (Fig. 3d). The configuration *symmetrical* is different because it has a stabilizing effect at  $s \approx 4$  and  $s \approx 6.5$  which are maxima. This is, however, a direct effect of the classification and due to situations when an *all-over* configuration turns into a *symmetrical* configuration. Still it is valid data within our classification scheme. To draw a direct connection to applications in ER we determine the potentials that are implied

by the average movement of species (for example, similar to gravitational potentials) which is here merely an integration over the average movement. Fig. 3f shows the 4 potentials of the 4 configurations (normalized to similar scales). These potentials are important findings for this study because they are emergent fitness functions with selective pressure towards bigger values in the same way as in the above schematic representations of the fitness functions for novelty search and MOBD (see Fig. 1). Similarly also here currently populated regions in beak-size space are less desirable and there is pressure towards unpopulated regions. For example, the potential for configuration *left* has a minimum at  $s = 3$  which corresponds to the typically populated position in this configuration as determined by low birth and death rates around  $s = 3$  (Fig. 3c and d) and an average motion of  $\Delta x = 0$  (Fig. 3e). These potentials are the confirmation that this self-organizing system certainly generates SPTD. While, for example, in novelty search that pressure is explicitly enforced by pushing towards behavioral diversity, here the selective pressure is a feature of the ecological system. Unpopulated regions in beak-size space correspond to big resources of energy in the form of seeds no one forages for. Birds that manage to push into these regions compete with few fellows, gather plenty of energy, and increase their fitness for survival. This analogy shows on the one hand that approaches based on behavioral distance should not just be considered as engineered abstractions but rather as bio-inspired approaches that have a direct connection to ecological features of speciation. On the other hand it shows an option of how to generate a self-organizing SPTD as discussed in the following.

## Discussion and Conclusion

In this paper we have detected self-organizing generation of SPTD in an AE and we have motivated the need for methods that generate diversity, particularly behavioral diversity in the field of ER. Standard methods to increase the diversity in a population but also recent methods based on behavioral distances include a considerable amount of a priori knowledge because they (tend to) include behavioral features in the definition of the behavioral distance that measure *how* the robot accomplishes a task. Mouret and Doncieux (2012) discuss the analogy between fitness function design and behavioral distance measure design: “More importantly, novelty search critically depends on a good behavior characterization to create a gradient. Researchers in ER used to craft fitness function to create a perfect fitness gradient; novelty search users have to craft the behavior distance to create a similar gradient. This last option may be easier for some problems but eventually some distances will be hard to define.” Hence,

even with methods not relying on fitness functions the former problem of including a priori knowledge about the task persists. Mouret and Doncieux (Mouret and Doncieux, 2012) discuss how the ideal setting for ER might look like: “In an ideal ER setup, ER researchers would only define a high-level fitness function and let the generic evolutionary process do the rest. This goal could be achieved with a generic behavioral distance function that could be used with most ER tasks while still improving the evolutionary process.” Whether such a generic measure of behavioral distances can be found is unknown. Instead we study diversity in natural evolution that is generated in a self-organizing process and our focus is on diversity by speciation. Due to limited biological knowledge about why species exist it is also difficult to determine prerequisites for the generation of diversity in artificial systems. Therefore we investigated the simple speciation model by Woehrer et al. (2012) and extended it to allow the evolution of features that define the process of sexual selection based on assortative mating. Our findings indicate that self-organizing speciation is achievable but the system is sensitive to parameter settings as known from other AE.

It seems difficult to provoke evolutionary dynamics that favor diversity over uniform solutions without imposing diversity by predefined environmental features (e.g., multi-modal distributions of seeds, see (Woehrer et al., 2012)). In fact it seems questionable whether sustainable generation of diversity is possible without stimulating influences from a dynamic environment or a complex ecology with intensive inter-species interaction. A beneficial finding is the analogy between methods based on behavioral distances in ER and the investigated self-organizing ecology in terms of the selective pressure that is generated. In both systems selective pressure is generated towards unpopulated regions of the search space (cf. Figs. 1 and 3f). Hence we follow that both systems relate to each other and that there might be a way of transferring the methods of generating selective pressure in AE to ER.

In the speciation model this selective pressure is an ecological feature because unpopulated regions of search space hold plenty of seeds which increase the fitness for survival once they are foraged. While this is easily implemented in this speciation model by defining a beak-size search space, it is unknown how distributing seeds in search space transfers as analogy to the behavior space of ER. This triggers an important research question: How to define AE in the context of ER that generate SPTD without explicitly addressing particular task-specific behavioral features and without including a priori knowledge. This could be done by a data structure that covers the full behavior space and keeps track of which regions of this abstract space have been vis-

ited (following the analogy: regions where most of the seeds have been eaten up). However, this would be most likely intractable and probably also task-specific. Solutions for this dimensionality reduction problem based on heuristics would possibly have similar difficulties as, for example, function approximation in reinforcement learning (Sutton and Barto, 1998). Presumably any method that maps behaviors from the actual behavior space into a smaller feature space will suffer from being either task-specific or of limited benefit although very simple mappings were shown to be beneficial in simple tasks (Mouret and Doncieux, 2009; Lehman and Stanley, 2008). Seemingly the statistics about the frequencies of behaviors is embedded into the environment in natural systems similarly to the concept of stigmergy in swarm intelligence. A candidate solution would be to evolve behaviors in an embodied system which allows for embedding behavioral statistics in the environment. Fortunately, an embodied approach is feasible in ER (Bredeche et al., 2012; Stradner et al., 2012).

Furthermore we have reported measurements (Figs. 3c-f) that allow for modeling speciation as a discrete birth-death process combined with a spatial feature determined by drifting motion towards unpopulated regions. That way speciation truly is linked “to rare stochastic events that cause reproductive isolation” (Venditti et al., 2010). In addition we have shown that the analysis of branch length distributions by Venditti et al. (2010) is also applicable in artificial systems and might prove to be instrumental in classifying artificial systems of speciation. In future work we plan to continue investigations of how to integrate AE into behavior space that is not task-specific and that generates SPTD in complex tasks for ER. In addition it might be desirable to investigate also models of speciation that evolve themselves features of sexual selection that generate diversity.

# Multi-Crease Self-Folding by Uniform Heating

Shuhei Miyashita and Daniela Rus

Computer Science and Artificial Intelligence Laboratory, Massachusetts Institute of Technology, USA  
shuheim@csail.mit.edu

## Abstract

This paper presents a self-folding method for multi-crease structures. The proposed method utilizes the symmetric breaking of a 3-layered two-dimensional sheet, where an inner contraction sheet induces shear force when heated, which directs the inclined folding direction. The fabrication technique developed enables distant placements of tiling patterns of the surfaces. The experimental result shows that by applying uniform heat, a feature with 62 folds can be simultaneously folded, an advantage over manual folding. The method presented is a new instant fabrication technique for making semi-rigid structures.

## Introduction

Biological entities achieve their fertile morphogenetic processes based on protein self-assembly and self-folding. Inspired by such processes, various attempts at the automated structuring of robot bodies have been made in the field of robotics. Hawkes et al. (2010) demonstrated self-folded ship and plane origami structures employing shape-memory alloy (SMA) actuators. Cheung et al. (2011) showed arbitrary 3D shapes that could theoretically be folded from a single strand. The underlying principle behind these approaches is assigning an individual actuator (i.e., shape memory alloy, or an electric motor) to each folding site. Thus, scalability of the system remains an open challenge. Recently, Onal et al. (2011) showed that the body of an insect-shaped, legged robot could be folded from a single laser-cut polyester sheet. MEMS technology employing a pop-up technique was proposed by Whitney et al. (2011). Felton et al. (2013) advanced Onal's model and incorporated the self-folding of a robot's body by assigning conductors around the hinges for localized heating by current application.

## Self-Folding Method

In this study, we use uniform heating to attain self-folding. We utilize thermal deformation of a contraction sheet (polyvinyl chloride, PVC) sandwiched by rigid structural layers with different gap widths, such that the shear force of a contraction layer induces a bending motion of the surface. We show the basic principle of the folding method in Fig. 1. Schematics of the fold are shown in side views on the left side in the figures, with corresponding snapshots on the right. The method is capable of (1) simultaneous mountain and valley

folds, (2) simultaneous multiple folds, and (3) coarse angle control by varying gap widths.

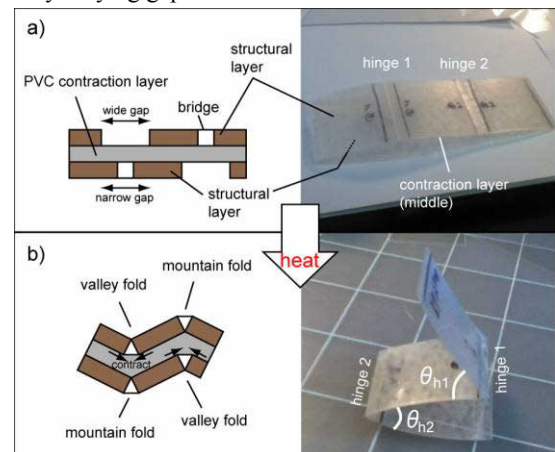

Fig. 1. Self-folding process by uniform heating.

## Accurate Folding Angle by Angle Fold

Attaining an arbitrary folding angle of a sheet structure is difficult at any scale, for it is dependent on the folding torque generated by the material. In order to attain accurate arbitrary folding angles, we focus on the kinematics of angle folds, specifically, the V-fold, in which one of the angles (termed output angle  $\theta_{out}$ ) can be precisely controlled by being kinematically coupled with another actuable angle (termed input angle  $\theta_{in}$ ). Since the derivative of  $\theta_{out}$  is small when  $\theta_{in}$  is small, in spite of the absolute change, the idea here is to “crudely” actuate  $\theta_{in}$  to exercise precise angle control over  $\theta_{out}$ . The concept for V-folds is illustrated in Fig. 2.

Fig. 2. Input angle and output angle in V-fold.

## Fabrication

Since the pattern of a structural layer involves multiple discrete tiles (islands), structural layers are cut out and placed on a semi-rigid backing layer. Once a laser makes the pattern, parts that position at gaps are manually peeled off. A contraction layer is then inserted and sandwiched by the backing-laminated structural layers, by folding it in half. Finally, the backing layer is removed from the structure, and the desired self-folding sheet is obtained.

## Result

The temperature control for the self-folding process is managed in an oven. To realize ideal uniform heating for the body, the sheet is hung from the ceiling. To demonstrate the advantage of self-folds, we chose an origami pattern that could only be folded if all the creases were folded simultaneously. This structure, which is shown in Fig. 4, consists of 62 mountain and valley folds.

Fig. 3 shows the self-folding process by uniform heating. Starting at room temperature and ramped up to 65 degrees, the process is complete in about 5 minutes.

Fig. 3. Self-folding process by “baking.”

The fabricated structure is shown in Fig. 4. The process, although applicable one time only, is reliable and fast. The method is suitable for types of fold that consist of many pleat patterns, because heat is applied to the entirety of the targeted material.

## Conclusion

This work presents the self-folding of a multi-crease structure by uniform heating. We first developed a technique that, by having different gap widths between a contraction layer, achieved the simultaneous folding of mountain and valley folds by heating the middle contraction layer. We further developed a fabrication technique, designing the island

features and placing them onto the contraction sheet. The self-folding process achieved is fast and reliable, and is promising for the fabrication of more complex structures.

Fig. 4. Self-folded structure, which consists of 62 mountain and valley folds.

### Abstract

The Artificial Reaction Network (ARN) is an Artificial Chemistry representation inspired by cell signaling networks. The ARN has previously been applied to the simulation of biological signaling pathways and to the control of limbed robots. In this paper we create multiple cell-like autonomous agents using ARN networks. It is shown that these agents can simulate some aspects of the behavior of biological amoebae. To demonstrate practical applications of such agents they are then reconfigured as a swarm of robots in a simulated oil spill clean-up operation. We demonstrate that ARN agents, like amoebae, can autonomously recognize environmental patterns and produce emergent behavior. The results show that such agents may be useful in biological simulation and furthermore may have practical applications in swarm robotics.

### Introduction

Unicellular organisms have evolved an astonishing array of complex behaviors. Some can avoid light with photo-sensitive spots; some actively hunt prey; while others can build protective shelters (Ford, 2009). It has been shown that single cells achieve such primitive intelligence by storing and processing information through the complex dynamics of interacting chemicals (Bray, 1995; Arkin and Ross, 1994). Within a cell, data is represented by a set of spatially distributed concentrations of chemical species; the instantaneous set of which corresponds to the cell's current state. Intricate networks of chemical reactions termed cell signaling networks (CSNs), process this information by transforming input species into output species. In this way, cells are able to respond to changes within their environment, communicate with other cells, and perform internal self maintenance operations. Several researchers highlight the processing capabilities of CSNs and their similarities to Artificial Neural Networks (ANNs) (Bray, 1995; Bhalla, 2003). For example, it has been demonstrated that a network of such reactions can perform Boolean and Fuzzy Logic functions and are equivalent to a Turing machine (Bray, 1995; Arkin and Ross, 1994). Furthermore, CSNs contain features such as feedback loops and interconnectivity, thus forming

highly complex systems (Bray, 1995; Bhalla, 2003). It is possible to exploit computational features of such chemical processing to create an Artificial Chemistry (AC). In its broadest sense, an AC describes a man-made system which is similar to a real chemical system (Dittrich, et al., 2001). The Artificial Reaction Network is an example of an AC and is based on properties and mechanisms found in CSNs. In our previous work, it was applied to simulate the chemotaxis signaling pathway of *Escherichia coli*, and later investigated as a means to produce complex temporal waveforms to control limbed robots (Gerrard, et al., 2011; 2012a; b).

In this paper, a single ARN network is instantiated and used as the internal control system for multiple instances of cell-like autonomous distributed agents. Our first objective is to show that ARN agents have application in the simulation of biological cells, their interactions, and resulting emergent behaviors. This is addressed by using the agents to simulate aggregating cells of the slime mould *Dictyostelium discoideum* and comparing the emergent behaviors with the literature. Our second objective is to show that by reconfiguring the inputs to each agent's ARN, the same agents can produce other distinct behaviors. Our final objective is to show that ARNs have application as the control systems for distributed robotic agents within real world environments. Here, we apply the agents to the task of cleaning up a simulated oil spill within a simplified search environment.

The paper is structured as follows: the first section provides an overview of the ARN representation. This is followed by an overview of the operation of the ARN agents. The experimental details and results are presented next; these are followed by the conclusions.

### The Artificial Reaction Network

In this section we provide a brief summary of the ARN representation. A full account can be found in our previous work (Gerrard, et al., 2011; 2012a; b).

The ARN comprises a set of networked reaction nodes (circles), pools (squares), and inputs (triangles) as shown in

figure 1. Each pool stores the current available chemical species concentration (avail); this concentration represents data within the system. Thus, the complete set of pool concentrations at time  $t$ , corresponds to the system's current state. Inputs are a special type of pool, the only difference being that they are not updated by flux at each time step, and are used to represent continuous concentrations, for example, environmental inputs or enzymes. Each circle corresponds to a reaction unit, representing a reaction between a number of chemicals. Data is processed by reaction nodes transforming incoming pool values to connected outgoing pool values. Connections symbolize the flow of chemical into and out of reaction units and their weight ( $w$ ) corresponds to reaction order. Connections provide the facility to create complex control structures using combinations of inhibitory and excitatory connections.

Figure 1: The Artificial Reaction Network representation.

$$\Delta C = \left( K_f(C) \left( A_{avail}^{W_A} B_{avail}^{W_B} \right) - K_r(C) \left( C_{avail}^{W_C} \right) \right) \Delta t \quad (1)$$

$$C_{avail} = C_{avail} + \left( \Delta C - \frac{W_C}{W_C + \alpha} \Delta D \right) \quad (2)$$

Where:

A, B, C, D = Species Concentrations

W = Reaction order (weight)

avail = Available species concentration

$K_f$  = Forward rate constant

$\Delta C$  = Change in species concentration C

$K_r$  = Reverse rate constant

$\alpha$  = sum of other incoming weights

Figure 1 shows the reaction between species A and B to produce species C. At time interval  $\Delta t$ , each reaction unit's temporal flux value is calculated by applying Euler's approximation to the differential rate equation given in (1). This value is then used to update the current concentration of each reaction's connecting pools as shown in (2). Pools may asymptotically approach 0, and thus below a particular threshold a pool is considered empty and its value set to zero. A reaction step may proceed if it meets its preconditions. Preconditions are met if incoming inhibitory pools are

inactive, and incoming excitatory pools are active. Similarly a reaction step will fulfill a number of post conditions: participating reactants are consumed and products generated—the amount of which will depend on the parameters of the reaction step.

## ARN Agents

This section describes the behavioral modes of each agent and the structure and operation of the ARN network controlling them. In the experiments outlined in this paper, a number of autonomous ARN controlled software agents termed "Cytobots" ("cyto" from Greek for cell, and "bot" from robot) are initialized and move around asynchronously within a 2D simulated environment containing a distribution of artificial chemicals. The artificial chemicals represent attractants of either food or cAMP (cyclic adenosine monophosphate). When an agent moves to a new position, the surrounding level of chemical is used to set the inputs to its ARN. Consequently this changes the internal state of the ARN and updates the agent's trajectory. During this process, the agent modifies the state of the environment by, for example, consuming food or releasing cAMP. Similar to the way in which a CSN acts as the control system to a cell, the behavior of each cytobot is controlled by its own instance of an ARN network. The ARN network architecture is based on a combination of functional structural motifs found in actual biochemical networks (Tyson and Novak, 2010). Each ARN instance is updated asynchronously with all other instances. In this way, each instance directs an agents' movement asynchronously to other agents, enables it to react to situated environmental patterns, and allows it to stigmergically communicate with other cytobots to contribute to higher level function.

The cytobot ARN network was designed to produce two simple behavioral modes: foraging and starvation, both are based on the movement patterns of single celled organisms as described in the following sections. The cytobot ARN is composed of 6 subnetworks as shown in figure 2. Each subnetwork contributes a functional aspect to either or both starvation and foraging behaviors. The subnetworks are discussed in the following sections.

### Cytobot Foraging Behavior

Cytobots forage by performing a biased random walk. This pattern of movement is exemplified by the bacteria *E. coli*, where foraging cells alternate periods of runs (forward motion) and tumbles (random redirections). By comparing concentrations of attractants and repellants in a temporal fashion, the organism is able to reduce the frequency of tumbles up concentration gradients of attractants, and down gradients of repellants, resulting in overall travel to more favorable conditions (Vladimirov and Sourjik, 2009). In the foraging mode a cytobot performs a similar random biased walk movement pattern. At each new position X, an agent redirects to a new random angle between 0 and 360 degrees (tumble). The agent then moves forward in a straight line for a number of time steps based on the level of detected food at position X (run). The cytobot consumes food (if present) at each passing location.

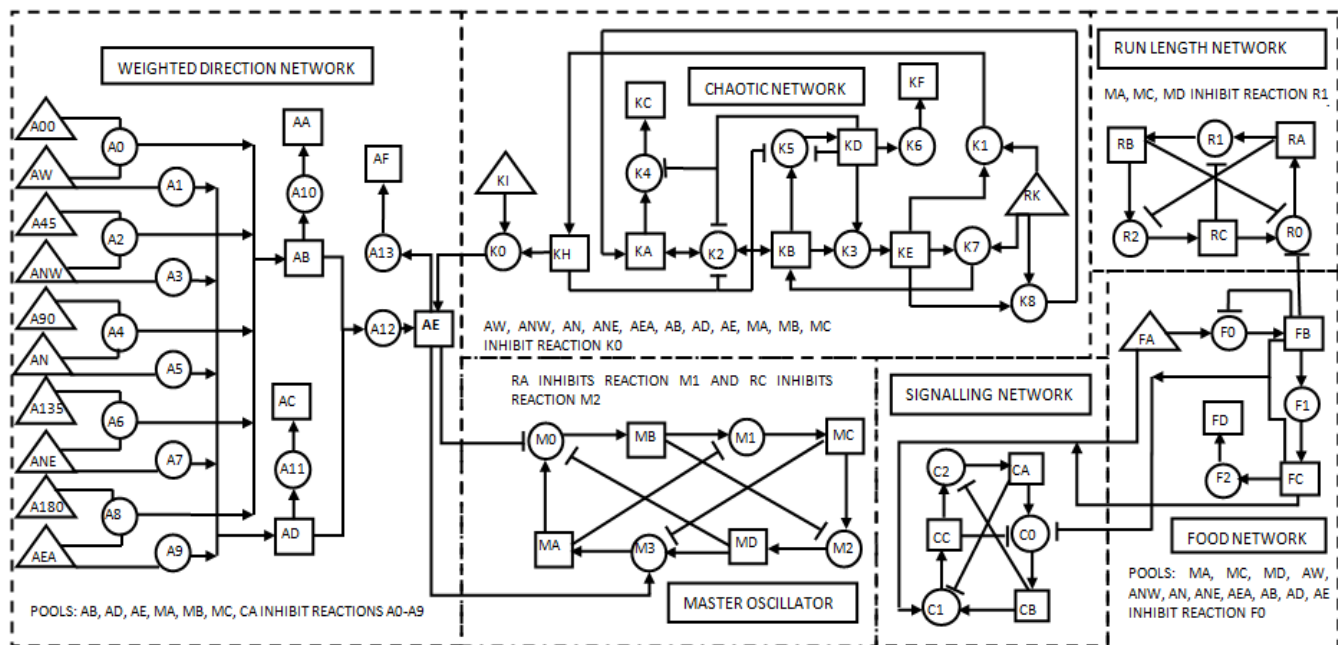

Figure 2: The cytobot ARN network comprising 6 subnetworks. Each cytobot is controlled by an instance of this network.

### Cytobot Starvation Behavior

The starvation behavior is based on the pattern of motion displayed by starving cells of the cellular slime mould *D. discoideum*. During the organisms' vegetative stage, cells move up gradients of folic acid secreted by its bacterial prey. When the food resource has been depleted, the amoebae begin to starve and enter the aggregation phase of their life cycle. During aggregation, starving cells secrete cAMP which serves as a signal to attract surrounding amoebae towards a central location (McCann, et al., 2010). During the aggregation phase, *D. discoideum* cells are polarized, thus one side becomes the leading edge which always faces in the direction of travel (McCann, et al., 2010). Depending on parameters such as environmental conditions, and the cell population density, migrating cells often form transient emergent patterns such as streams, waves and spirals (McCann, et al., 2010; Dallon and Othmer, 1997). Streaming describes a pattern of motion where cells line up in close order files, with the head of one following the rear of another (McCann, et al., 2010).

In these experiments the agents enter starvation mode if food has not been consumed within a time period. Here, instead of turning in a random direction, the new direction is weighted toward the highest concentration of cAMP within its surrounding area. As discussed later, by representing the external chemicals in different ways within the simulated environment, different high level behaviors can be produced by the agents.

### The Master Oscillator

The master oscillator network (see figure 2) functions to synchronize all the outputs from all the other subnetworks together and is what each agent references at each time step to ascertain its current behavior. It is a simple closed loop, with

a token unit of chemical cycling around it. It consists of 4 reaction units: M0, M1, M2, and M3 (all with reaction rate of 1) and 4 pools MA, MB, MC and MD. Each pool activates one of three behaviors, and for every time step that a particular pool contains the token unit, its corresponding behavior is performed. Pool MA activates turn, MC activates run and pools MB and MD activate stop. If these pools were switches to motor actuators on a simple wheeled robot, pool MC would switch on all wheel motors, while pool MA would switch on wheel motors on the left side only, thus turning the robot. The remaining pools would act as off switches. The other subnetworks inhibit or excite the reaction units of the master oscillator to allow or prevent chemical flow. The number of time steps that a chemical is present in a particular pool indicates the length of time that a particular behavior is performed. Thus if pool MC contains a chemical for 10 time steps, then the agent will move forward for 10 time steps; similarly if this were pool MA, the agent would turn for 10 time steps.

### The Food Network and the Run Length Network

The food network senses the level of food within the environment and connects to the run length network to modify the number of steps forward according to the level of food sensed. The value of food at a cytobot's current position is stored at input pool FA. The forward rate of reaction node F0 is 1, thus all food is transferred to pool FB in a single time step. The presence of chemical in pool FB inhibits the run network reaction R0 for a number of time steps according to the level of food (by setting forward rate of unit F1 to 1 and weight to 0 this can be an exact correlation). This in turn stops pool RC in the run length network from emptying. Pool RC inhibits reaction M2 of the master oscillator thus preventing pool MC from emptying for the same number of time steps.

As discussed previously, the number of time steps which pool MC contains the token unit represents the number of time steps to move forward.

### The Signaling Network

The signaling network functions as a switch between starvation and foraging mode. Low food levels trigger the starvation response and allow the weighted direction network to control each new angle. Sufficient food will switch off the weighted direction network and allow the chaotic network to control each new angle. It is a simple closed loop with a token unit of chemical flowing around it. Pool CA acts as a switch between foraging and starvation behavior, where the presence of chemical in CA inhibits the weighted direction network; while its absence switches on the weighted direction network; this in turn inhibits the chaotic network, as shown in figure 2. In this component, all reaction units have a forward flux of 0.5; which ensures a minimum number of time steps for each behavior.

### The Weighted Direction Network

The weighted direction network senses cAMP within the agent's immediate environment and calculates a tumble angle which is weighted toward higher cAMP levels. This network interfaces with the environment via a number of receptor pools (AW, ANW, AN, ANE, AEA) which sense the level of cAMP around the cytotob. These pools represent receptors positioned at fixed points around the front of its perimeter. Limiting the signal detection to one side facilitates representation of polarization in *D. discoideum*, where that side becomes the leading edge. For each receptor input pool, there is a static pool containing a fixed level of chemical which represents the angle of the receptor relative to the cytotob. Directions start from AW (west) with a corresponding numeric value of 0 (A00) and progress in 45 degree steps through each direction to east (thus maximum value is 180). Detected signals are classed as being in one of the following cardinal/ordinal directions: W, NW, N, NE, and E. Thus signals are detected from all directions above its horizontal plane. All connections have a weight of 1 with the exception of the connection between pool AD and reaction A12 which has a weight of -1. This negative connection raises the sum of chemical detected in pool AD to -1, which multiplied by AB, allows the average angle to be calculated. The calculated angle interfaces with the remaining subnetworks at pool AE. In an actual organism, receptors are set around the cell perimeter and direct movement appropriately.

$$h \equiv ((n - 90) + c) \bmod 360 \quad (3)$$

Where:

h= new heading (relative to external frame)

n = count of time steps pool MA contained chemical

c = current heading (relative to the external frame)

In this simulation, for simplicity, a count of the number of time steps that MA contains the token unit is processed to

gain the turn angle using (3). Thus if the number time steps is 120 and the agent is facing north, then the current heading would equal 0 (relative to the external frame) and the new heading would equal 30.

### The Chaotic Network

The chaotic network, as shown in figure 2, is responsible for generating pseudo random angles which agents use to perform the foraging tumble behavior. It is a networked implementation of a Logistic Map, see (4). Ulam and von Neumann (1947) were the first to examine a Logistic Map as a pseudo random number generator and it has been successfully used in this capacity by several researchers (Patidar, et al., 2009). The probability density distribution of the Logistic Map is non-uniform and is given in (5).

$$X_{n+1} = \lambda X_n(1 - X_n) \quad (4)$$

Where:

$X_n$ = state variable of value  $0 \leq X_n \leq 1$

$\lambda$ = system parameter of value  $1 \leq \lambda \leq 4$

$$P(X) = \frac{1}{\pi \sqrt{X(1-X)}} \quad (5)$$

Where:

P(X) = probability of X occurring

At the start of the simulation, pools KA and KB of each cytotob's chaotic network are initialized to the same random value between 0 and 1 (to 5 decimal places). This value represents the first value of X (where X represents the state variable of (4)). All the other pools are initialized to 0 with the exception of the static pools KI and RK whose initial values are 360 and 1 respectively. Reaction K2 is responsible for generating each new value of X and has a forward and reverse rate of 4 (the logistic map exhibits chaotic behavior when  $\lambda$  is 4). The connection between KA and K2 has a weight of 1 and the connection between K2 and KB has a weight of 2. The remaining series of reactions function to copy the value of X 3 times, where 2 copies serve as the new initial values of KA and KB and the remaining copy participates in the final output of the network at KH. Static pool KI has a fixed value of 360 which in reaction K0, allows the network to convert the pseudo random number at KH to an angle value between 0 and 360. However, reaction K0 cannot proceed until all 11 pools that inhibit it are empty. These inhibitory connections ensure that random angles are not output while the agent is in starvation mode, and that pool AE is empty before adding more chemical.

## Slime Mould Aggregation Simulation

In the following experiments cytotobs are used to model the behavior of aggregating *D. discoideum* cells, where each cytotob represents a cell. In each experiment the emergent patterns, numbers of mounds, and length of time to mound formation is examined. A total of 10 experiments are performed at varying population densities of cytotobs (p) and

different ranges of detection of cAMP ( $r$ ), as shown in table 1. The environment contains no food, thus each agent immediately enters and stays in the previously described starvation mode. The agents' behavior is initially explored at biologically realistic  $p$  and  $r$  values and compared with the behavior of the actual organism and other simulations. These parameters are then extended into ranges outwith the biological range in order to examine the emergent properties of the system.

```

FOR each cytotobot
  Get current agents' facing direction  $C_F$ 
  Assign a value to direction  $C_F$  using statement 1

  FOR each (index  $n$ ) detected cAMP signal
    Get detected signal incoming direction  $C_A$ 
    Assign a value to direction  $C_A$  using statement 1
    IF  $C_A = C_F$  THEN  $k_n = 3$ 
    ELSE IF  $C_A = C_F - 1$  OR  $C_A = C_F + 1$  THEN  $k_n = 2$ 
    ELSE IF  $C_A = C_F - 2$  OR  $C_A = C_F + 2$  THEN  $k_n = 1$ 
    ELSE  $k_n = 0$ 
    END IF
    Calculate distance  $d_n$ 
    Store each  $C_A$  with  $k_n$  and  $d_n$ 
  END FOR

  Calculate  $W_A$  for current agent using Equation 6
END FOR

Statement 1: East = 1; North East = 2; North = 3; North West = 4; West = 5

Where:
 $W_A$  = total weight of direction A
 $N$  = total number of agents within range of detection
 $d_n$  = distance of current agent from agent  $n$ 
 $C_A$  = direction of incoming signal detected by current agent
 $C_F$  = the current agents facing direction
 $k_n$  = value of cAMP signal from agent  $n$ 

```

Figure 3: Pseudocode to calculate the strength of detected cAMP at each direction relative to the cell.

$$W_A = \sum_{n=1}^N \frac{k_n}{d_n} \quad (6)$$

Cytobots move within a simulated 2D environment of area  $5.06 \text{ mm}^2$ - approximately half the maximum recorded aggregation territory reported in the literature (Dallon and Othmer, 1997). Each pixel represents  $4.5 \text{ }\mu\text{m}$  and the grid is  $500 \times 500$  pixels, giving a total area of  $5.06 \text{ mm}^2$ . In nature, aggregating *D. discoideum* cell densities are typically 250 per  $\text{mm}^2$  to  $1 \times 10^4$  per  $\text{mm}^2$  (Dallon and Othmer, 1997). Due to the computational resources required to manage a population of cytotobots within the upper range, two cell densities of 250 agents per  $\text{mm}^2$  (1250 agents) and 150 per  $\text{mm}^2$  (750 agents)

were chosen. The agents are initialized at random positions within the simulated environment. Each starving agent emits a cAMP signal at equal strength around its circumference into the environment. This signal is detected by other agents within or equal to  $r$ . In these experiments a range of  $r$  values are explored, including that of real cells of 1, 0.5, and 0.1 mm (McCann, et al., 2010). The actual cAMP signal degrades linearly with increasing distance ( $d$ ) from the emitting cell. Each agent detects the cAMP signal of all starving cells within or equal to  $r$ , and a total value for each direction ( $A$ ) is calculated using the pseudocode given in figure 3. Each cycle represents 1 minute of time. In this time the agent moves  $9\text{ }\mu\text{m}$ - a distance which corresponds to that reported in the literature (Rifkin and Goldberg, 2006). Therefore, after 1 hour motion the agent travels a distance of  $540\text{ }\mu\text{m}$ . In reality there are always remaining cells that do not aggregate, and thus the simulation runs until 95% of agents are at a distance of less than 0.1mm from their nearest neighbor.

## Results

The results for all 10 experiments are given in table 1. Each experiment was performed 100 times. In experiments 8, 9, and 10 the value of  $r$  and  $d$  are within the ranges reported for real *D. discoideum* cells. These experiments are used to compare the behaviors and length of time taken to aggregate with the literature. In experiments 8, and 9 aggregation completes after an average formation of 4.3 mounds in 10.05 hours, and 6.7 mounds in 12.65 hours respectively. In nature the organism takes between 9-13 hours to aggregate (Cotter, et al., 1992; Becker, et al., 2010), thus the results of these experiments have an aggregation time within the reported range. This is also comparable to other simulations. For example, Becker et al. (2010) reports an aggregation time of 11.6 hours for a simulated population of *D. discoideum* with a cell density of  $200\text{ mm}^2$ . In experiment 10, the population never satisfied the criteria for completion of aggregation, where instead the agents appeared to move in a fashion reminiscent of Brownian motion. The likely explanation for this is twofold. Firstly, the simulation does not consider the effect of glycoproteins where aggregating cells making contact with each other attach together. Secondly, because the attraction range is so small, agents are only able to detect other agents within their immediate neighborhood, thus momentarily larger clusters with higher attraction strength go undetected and quickly dissipate- an effect that would not occur if agents stayed together. The complete set of results shows that by increasing  $p$  by  $100\text{ mm}^2$  the number of mounds formed at each  $r$  decrease with the exception of experiment 6. This is not surprising, as denser populations should have more chance of interacting, and thus form fewer clusters, but with higher numbers of agents. Similarly, decreasing  $r$  results in a general increase to the number of mounds formed at both values of  $p$ . The likely reason for this is that as  $r$  decreases the agent becomes unable to influence increasing quantities of area, thus larger numbers of stable clusters can form but with fewer numbers of agents.

Emergent behaviors and clustering patterns similar to the biological organism were also observed. As previously discussed, the cytotobots are polarized.

| 5  | 150                             | 0.1             | 14.2<br>(2.36)                              | 10.6<br>(1.82)                                                |
| 6  | 250                             | 5               | 1<br>(0)                                    | 8.95<br>(0.11)                                                |
| 7  | 250                             | 2.5             | 1<br>(0)                                    | 9.6<br>(0.20)                                                 |
| 8  | 250                             | 1               | 4.3<br>(0.37)                               | 10.05<br>(0.58)                                               |
| 9  | 250                             | 0.5             | 6.7<br>(1.62)                               | 12.65<br>(1.94)                                               |
| 10 | 250                             | 0.1             | -                                           | -                                                             |

Implementing the agents in this way allowed us to observe whether or not the previously described streaming behavior occurs. A close up of the right hand corner of screenshot C is shown in figure 4G showing agents beginning to form a cluster. The protruding head of each agent can be seen clearly, where each lines up its head to the rear of another agent and forms a stream. As can be seen in figure 4F this is very similar to the streaming behavior in real cells of *D. discoideum*. Other emergent patterns occurred during different experiments including spirals (figure 4H), symmetric patterns (figure 4I), and waves (figure 4J).

### Oil Spill Clean-up Simulation

To illustrate a practical application, the cytotobots are used to tackle a simplified oil-spill clean-up simulation. In these experiments, the same ARN used previously produces different behaviors by altering its interface with the environment. In the following 4 experiments the length of time it takes for 3, 5, 8 and 15 cytotobots to clean up 95% of the oil is recorded. These results are compared with similar work.

The cytotobots move within a 2D simulated environment containing an oil spill. This oil is analogous to a distribution of food within a nutrient landscape. The task of the cytotobots is to clean up the spill as quickly as possible by consuming oil at each location. The agents move through the environment by switching between the two previously described behavioral modes- foraging and starvation. In the aggregation experiments, no food was present, thus the foraging behavior remained inactive. In this case, the concentration of oil surrounding the agents was fed into both the receptor pools of the weighted direction network and the food network. Thus in this case oil represents both food and cAMP. At the start of each experiment, the cytotobots are distributed randomly within the environment, and the ARN network is initialized as previously described. The agents start the simulation in foraging mode but during the simulation alternate between foraging and starvation modes. Starvation behavior is triggered after the most recent positions (minimum of 2) contained zero food. In starvation mode, instead of turning in a random direction, the new direction is weighted toward higher concentrations of food within its surrounding area. This behavior forces exploration of unexplored search space because previously visited positions have a food level of 0. Consumption of environmental food therefore acts as a stigmergic signal, where agents are inclined to move up the nutrient gradient created by their foraging activities. Here, we

model the spillage of 100 tonnes of Statfjord crude oil at  $15^{\circ}\text{C}$  under a wind speed of  $5\text{ms}^{-1}$ . The oil is distributed over a 2D sea surface of  $300\text{m}$  by  $200\text{m}$ , thus an area of  $60000\text{m}^2$ , where 2 pixels corresponds to  $1\text{m}$ , as shown in figure 4A. This particular oil type and parameter set were chosen in order to compare directly with work by Kakalis and Ventikos (2008) who present a robotic swarm concept for oil spill confrontation. For this reason, we account for an initial response time of 14 hours. Based on the complex mathematical models found in Kakalis and Ventikos which account for the main factors of short term changes in oil characterization, the volume of oil after 14 hours is reduced to  $150\text{m}^3$ . Beyond the starting state, the volume is only influenced by the cytobots. The speed of each agent is  $0.5\text{ms}^{-1}$  and is based on other robotic agents in oil cleaning scenarios (Kakalis and Ventikos, 2008), thus the cytobots move 1 pixel ( $0.5\text{m}$ ) for every time step. The actual cleaning surface is  $1\text{m}$ , thus the cytobots clean a 2 pixel wide area in each time step.

Mathematical modeling of an oil spill is non-trivial and at best can offer a crude approximation of its actual trajectory. Most oil spills quickly form a comet shape with most of the oil within the head and a trail of sheen (Wang and Stout, 2007). To represent a simplified version of the comet shaped spread, the area is divided into  $100\text{m} \times 200\text{m}$  segments. The first segment contains  $0.015$  tonnes of oil, and each subsequent segment increases by  $0.03$  tonnes from right to left.

## Results

In each experiment, a different number of cytobots was deployed- 3, 5, 8 and 15 and the recovery rate achieved by each group was compared. The simulation time was measured from deployment of the cytobots at 0 hours (14 hours after oil was spilled) and stopped when the cytobots had collectively removed 95% of the  $150\text{m}^3$  of oil. Each experiment was run 100 times, and the average volume of oil consumed at 6 minute intervals was calculated. Figure 6 presents the volume of oil consumed by each group of cytobots against time. The finishing times in hours are 15.2, 11.5, 9.6, and 6.1 for 3, 5, 8, and 15 cytobots respectively. By adding 2 additional agents to the group of 3 the length of time is reduced by 3.5 hours, thus  $1.75$  hour difference per extra cytobot. This difference decreases  $1.12$  hours per cytobot for 8 agents, then to  $0.76$  per agent for 15. This variation can be accounted for by examining the agents' paths through the oil. Rates are much faster at the beginning of the experiments, where cytobots move toward the oil rich left side of the environment. This can be seen in the series of screenshots in figure 5 where A shows the starting position at time 0, and B shows that after 2 hours the cytobots have moved toward the left-hand side, focusing mainly on highly concentrated areas (consumed oil is shown in white). Initially, the rate of oil removal is high because cytobots focus on the volume rich areas and cannot go over their path, thus each new location results in consumption of oil. However, as time progresses, large patches become cleaned and a higher probability exists for the cytobots to revisit previously cleaned areas. The consumption of oil in figure 5 C and D at 4 and 9.6 hours respectively shows more clearly that cytobots focus cleaning efforts on the richest volume area first, and are gradually forced to move

toward the next highest concentration by the gradient created by their foraging activities.

Figure 5: Oil simulation using 8 cytobots at A- 0 hours, B- 2 hours, C- 4 hours and D- 9.6 hours

Figure 6: Volume of oil cleaned against time for each group of cytobots

Figure 5 D shows the state of the oil at the end of the simulation, where only small patches remain mainly in areas of low oil volumes. These results can be compared to the simulation by Kakalis and Ventikos. Here, varying numbers of simulated EU-MOP robots are deployed to tackle  $150\text{m}^3$  of Statfjord oil over  $60000\text{m}^2$  (as before). In this case, the robots have a slightly faster speed of  $0.54\text{m/s}$  but have the same  $1\text{m}$  skimming face. Each EU-MOP robot has a storage capacity of  $2\text{m}^3$  and a transit speed of  $2.1\text{ms}^{-1}$ . The time taken for 3, 5, 8, and 15 EU-MOPS are 54, 32, 20 and 10 hours respectively. For comparison, the results of our simulation can be adjusted to include unloading of the oil at a servicing vessel. Using the same storage capacity and transit speed and assuming the distance to the ship and back is 2 times  $300\text{m}$  and that each cytobot fills the same amount simultaneously, then the new times are 17.2, 12.7, 10.3 and 6.5 for 3, 5, 8 and 15 cytobots respectively. The Kakalis and Ventikos simulation has several differences to the one reported here, particularly in the distribution of the oil. Also, some key parameters are missing from their paper, for example, distance to boat. Despite these

differences, our results are very similar. For example the reported simulation time for 15 EU-MOPS is 10 hours and in our simulation 5 and 8 cybotbots took 12.7 and 10.3 hours respectively. Given the differences in the simulation and differences in operation of the robots, the resulting clean up times are comparable showing that the cybotbots have potential application as distributed robotic agents in real-world environments.

## Conclusions

The aggregation experiment results presented above show that the agents are able to simulate behavior of individual unicellular organisms, and model emergent behavior arising from interactions among such groups. These results demonstrate the parallels between ARN agents and the biological counterpart from which they were inspired. It also highlights a potential use as a means to simulate groups of interacting cells such as a bacterial colony or tissue component within a multicellular organism.

The results for the oil spill simulation demonstrate potential application for the ARN agents as autonomous agents within real world environments. This application demands an internal control system which can function without reference to other agents within the environment which are operating in parallel. By modifying the environment, (which in this case was consumption of food), the agents can stigmergically communicate and facilitate emergent behavior. The cybotbots offer a unique range of abilities. Like cells, their internal network of spatially distributed dynamic chemical species allows them to autonomously coordinate and direct their movement, recognize and respond to patterns in the environment, and produce high-level behavior.

In future work, it is intended to further explore the AI applications of the cybotbot agents, and later, to create swarms of cybotbot robots with applications in real world environments.

## Abstract

The emerging field of *morphological computation* seeks to understand how mechanical complexity in living systems can be advantageous, for instance by reducing the cost of control. In this paper we explore the phenomenon of morphological computation in tensegrities – unique structures with a high strength to weight ratio, resilience, and an ability to change shape. These features have great value as a robotics platform, but also make tensegrities difficult to control via conventional techniques. We describe a novel approach to the control of tensegrity robots which, rather than suppressing complex dynamics, *exploits* them in order to achieve locomotion. Our robots are physically embodied (rather than simulated), evolvable, and locomote at higher speeds (relative to body size) and with fewer actuators than those controlled by more conventional approaches.

## Introduction

Traditional engineering approaches to design of structures and the control of robots attempt to avoid, or at least actively suppress, complex system dynamics such as vibration and dynamic coupling among components. By reverting them to generally rigid and holonomic systems, their kinematics can be modeled using classical mechanics (Murray et al., 1994; Sciavicco and Siciliano, 2000), and these models can in turn be used to generate desired movements.

By contrast, the bodies of many natural organisms (and robots which attempt to mimic them) are by their very nature high dimensional dynamic systems with an essentially infinite number of degrees of freedom. Properties of living systems such as elasticity and deformability come at the cost of resonances and tight dynamic coupling between components (Trimmer, 2007) – properties which are often assiduously avoided in conventional engineering approaches to robotic design. This precludes the use of most of the traditional kinematic and inverse-dynamics approaches described above (Craig, 1989). While some methods exist for the control of non-holonomic (under-controlled) mechanical systems, many are incredibly computationally expensive, and difficult to transfer from simulation to reality (Hannan and Walker, 2003; Fung, 1993; Vogel, 2003).

How then, are dynamically complex biological systems so controllably robust and agile? The emerging field of *morphological computation* (Paul, 2006; Pfeifer et al., 2007; Pfeifer and Bongard, 2006) conjectures that “outsourcing” the computation into the mechanics of the structure allows related neural pathways to devote their resources to higher level tasks (Valero-Cuevas et al., 2007) – a type of “intelligence by mechanics” (Blickhan et al., 2007). These phenomena have been shown in the physiology of animals such as wallabies (Biewener et al., 2004) and guinea fowl (Daley and Biewener, 2006) and cockroaches (Ahn and Full, 2002).

Biological morphological computation has served as inspiration for robotic control in several recent works. Iida and Pfeifer (Iida and Pfeifer, 2006) explored how the body dynamics of a quadruped robot can be exploited for sensing. Watanabe (Watanabe et al., 2008) demonstrated how inducing long distance mechanical coupling in a snake robot improves its ability to learning a crawling motion. All of these systems were largely composed of rigid elements. Our interest is expanding these principles into the realm of soft materials and structures, where the complexity, and therefore the potential for beneficial exploitation, is significantly higher.

This paper demonstrates morphological computation in tensegrity robots. Tensegrities, pre-stress stable structures composed of rigid struts and tensile springs, possess many appealing traits, but exhibit high degrees of mechanical coupling, and are therefore difficult to control through conventional means. We implement an alternative and novel approach to tensegrity locomotion, one which seeks to exploit, rather than suppress, vibration and dynamical coupling between components. The resulting robot is quite simple, with open-loop actuation by low-voltage vibrating pager motors, and yet is capable of robust and controllable motion. We believe this to be both the fastest and the smallest physically embodied tensegrity robot yet to be developed. We begin the paper by describing the design of the robot. We then demonstrate vibrationally-actuated gaits which produce linear and rotational behavior. These gaits can be sequenced together in order to generate controllable trajectories. We conclude by discussing more sophisticated control algorithms and op-

timization techniques.

## Tensegrity Robots

A tensegrity structure (Figure 1) is a self-supporting structure consisting of a set of disjoint rigid elements (struts) whose endpoints are connected by a set of continuous tensile elements (springs). Despite the fact that none of the rigid elements touch, tensegrities are able to maintain their structure due to a synergistic interplay of compressive and tensile forces (Wang, 1998). Because of this *pre-stress stability*, they are able to quickly return to form when perturbed by an outside force. (Connelly and Back, 1998).

Examples of tensegrity can be found in structures ranging from camping tents to sports stadiums. These same principles are also found in the biological realm, at all scales from the structure of proteins (Ingber, 1998) and cellular cytoskeleton (Wang et al., 2001) up to the tendinous network of the human hand (Valero-Cuevas et al., 2007).

What makes tensegrities particularly appealing as a robotic platform is their high strength-to-weight ratio and resilience, as well as their ability to change shape by altering the resting length of the tensile elements. As a result, tensegrity structures are increasingly being used for applications such as smart structures and soft robots (Tibert and Pellegrino, 2003; Tibert, 2002; Motro, 2003; Sultan, 1999; Matsuda and Murata, 2006).

Unfortunately, the pre-stress stability of tensegrities imposes complex nonlinear dynamics, even for relatively small structures (Skelton et al., 2001). Conventional approaches to tensegrity robots therefore attempt to dampen the vibrational modes of the robots before controlling them. Skelton *et al.* have been able to demonstrate both active vibration damping (2004) and open-loop control of simple structures (2004).

In most cases, once the vibration and dynamical coupling of a tensegrity robot has been reduced either actively or passively, deformation and control are achieved by changing the rest lengths of the tensile elements, for instance by attaching strings to a reeled servo motor (Paul et al., 2006, 2005). Even so, the majority of tensegrity robotics has occurred in simulation (Aldrich et al., 2003; Paul et al., 2006; Graells Rovira and Mirats Tur, 2009; Iscen et al., 2013) rather than reality (Shibata et al., 2009). One notable recent contribution is Caluwaerts *et al.*'s work (2013) on physical reservoir computing in a simulated tensegrity robot, in which they demonstrate learnable gaits produced by relatively simple central pattern generators (CPGs).

There are a few published examples of physically embodied tensegrity robots moving. Paul *et al.* (2006) built a three-bar tensegrity robot with 0.4m struts, with three of its tensile elements actuated by servomotors. Using a gait derived from simulation, the physical robot was able to achieve speeds of around 60cm/min. Shibata *et al.* (2009) built a 6-bar tensegrity with 15cm struts, with its tensile elements actuated by shape-memory alloy wires. (The speed of the

Figure 1: Tensegrities consist of a set of rigid elements (rods) joined together by tensile elements (springs). They maintain their shape through a synergistic interplay of forces. (Photo by Steven Stangle)

resulting robot was not published). Later, Koizumi *et al.* (2012) built a six-bar robot with 0.6m struts with tensile elements actuated by 24 pneumatic McKibben actuators, which moved by rolling. While the speed of the robot is not published, an online video shows 15 rolls in the space of 45 seconds (1 roll per 3 seconds). We estimate from the video that the robot is moving at approximately 25cm per roll, or 5m/min.

## A new way to move tensegrities

The approaches describe above have essentially treated tensegrity-based robots as quasi-static and non-oscillating structures. And yet, tensegrities are by their very nature highly dynamic – anecdotally, the tensegrities we have built in our lab will readily oscillate as the table is bumped, or even as someone types on a keyboard.

The motivation for our work, therefore, lies in striving to exploit, rather than suppress, this inherent dynamical complexity as an advantage – making tensegrities move by vibrating, rather than suppressing their vibrations. Since the dynamics of real-world tensegrity structures are incredibly difficult to model in simulation, we chose to avoid simulation entirely and perform all experiments in the physical world. Quoting Rodney Brooks, “the world is its own best model” (Brooks, 1990).

## Design

Our ambition was to design a small (< 15 cm) tensegrity that was powered by vibration alone. It would also have to be robust enough to endure the long hours of testing and, given the practical challenges of constructing a mechanical device on so small a scale, it would be advantageous if it were easy to manufacture and repair.

The resulting design, based upon a canonical six-bar tensegrity shape, is shown in Figure 1. The geometry is

Figure 4: Max distance (over 10 evaluations, each lasting 7 seconds) traveled by the robot during a sparse sweep of voltages for motors 1 and 2 between 2.1V and 2.9V, in increments of 0.3V (motor 3 was fixed at 0V). As can be seen, the resulting space is complex, and distance does not correlate directly with motor speed.

Figure 5: Variation across trials for a sweep of motor 1 values while keeping voltages for motors 2 and 3 fixed (the bottom row of Figure 4))

Figure 6: An example of how distance traveled was automatically measured. Position was calculated by subtracting an “empty” arena image from one containing the robot. Distance could then be measured by comparing beginning (left) and final (center) robot positions (right).

Figure 2: The robot testing arena is on the floor in order to maximize the navigable area. (Photo by Steven Stangle)

Figure 3: The body of the tensegrity robot consists of rigid plastic rods and metal springs. It is actuated by simple DC vibrating motors attached at the midpoint of three of its six struts. A closeup of the robot illustrated the springs and the DC motors. (Photo by Steven Stangle)

defined by six equal length composite struts which are connected to each other via 24 identical helical springs, with four springs emanating from each strut end.

This 6-bar tensegrity has three orthogonal planes of symmetry. As a result of this natural symmetry, each spring wants to stretch an equal amount in the fully assembled equilibrium configuration, greatly simplifying design and analysis. There is however a slight loss of symmetry when the tensegrity is placed in contact with the ground because none of the stable contact positions are aligned with the planes of symmetry. Sagging of the springs under the weight of the spars and motors further disrupts the symmetry. Three small vibration motors were mounted on composite struts and oriented such that each shaft axis is perpendicular to one of the planes of symmetry.

Few actual machining operations are required to produce the tensegrity. The 9.4 cm long composite struts are cut from 6.35 mm square graphite composite tubes. The motors were mounted to the flat outer surface of the struts using epoxy. The struts, while square on the outside, are hollow circular on the inside. Therefore, both ends of each strut could be tapped to allow for insertion of 10-24 nylon screws. These screws provide a smooth contact surface for the tensegrity to rest on and are used to fasten nylon washers to the ends of the struts. The hooked ends of the helical springs are attached directly to the nylon washers via 4 equally-spaced drilled holes.

Selection of the springs is critical to overall performance. The basic strategy was to try to produce the smallest possible natural frequencies under the presumption that small natural frequencies would lead to large displacement amplitudes, thus enhancing the chances that the tensegrity might roll. We strove to achieve this goal by minimizing spring stiffness and spring preload subject to the constraint of keeping static deflections within an acceptable limit (so that the tensegrity would not lose its basic shape). A single vertical strut was modeled as supported by eight linear springs oriented at  $45^\circ$  in order to limit the maximum static deflection

to 5% of total strut length. This calculation led to selection of a helical spring with a spring constant of 0.209 N/cm.

Attempts were also made to optimize the selection of a vibration motor. While the need for a small motor with a relatively large offset mass was clear, choosing the best range of operating speeds involved compromise. On the one hand, the motor speeds have to be large enough to produce sufficient centrifugal force, but also small enough to excite the lower (high energy) natural frequencies of the tensegrity. These considerations led to selection of the Precision Microdrives vibration motor Model 312-107 (Figure 3) which operates between 100 and 260 Hz.

To check the suitability of this operating range, the tensegrity was modeled using a matrix structural analysis code. One end of one strut was assumed fixed in space and the associated natural frequencies were determined. The fundamental (lowest) frequency was found to be 7.8 Hz, well below the operating range of the motor. However, physical testing of the tensegrity with these motors indicated the existence of natural frequencies that were within the operating range.

## Evaluation

Having designed the robot in order to maximize resonance, we then evaluated its ability to locomote via vibration. Early trials indicated a wide diversity of motions was possible, and that small changes in motor frequencies could lead to large changes to the resulting gait. Below we seek to quantify this.

(Videos of the robot moving can be seen at the corresponding author's web page: [www.cs.union.edu/~rieffelj/videos/](http://www.cs.union.edu/~rieffelj/videos/))

## Setup

The robot was placed into an 85cm x 80cm arena (Figure 2) on the floor of our lab (the robot had a habit of falling off of tables) and tethered to the power supply and motor controllers. In order to reduce the effects of the tether, which might undesirably constrain the motion, the tether was built from narrow gauge magnet wire. Two cameras, a USB camera and a small handheld video camera, were placed 130cm above the arena. The USB camera was used for distance measures and the video camera was used to document results.

The voltage (speed) of each of the three motors was controlled by USB motor controllers connected to a host computer.

As illustrated by Figure 6, the process of distance measure was automated using the overhead USB camera connected to the control computer. The location of the tensegrity in a frame was determined by subtracting the image of an "empty" arena from an image containing the robot and then finding the centroid of the remaining pixels. The tether is visible in some frames, but has a negligible impact upon positional measurements. Distance could then be calculated

by comparing the pre- and post-evaluation locations. The arena was large enough that multiple evaluations could often be performed before manually returning the robot to the center of the arena.

## Two-Motor Gaits

In order to demonstrate the diversity of gaits produced by the tensegrity robot, we ran a sparse sweep of motor voltages for two motors between 2.1V and 2.9V, keeping the third motor fixed at 0V (voltages below 2.0V do not produce motion in the motors). Each frequency set was evaluated over ten trials, each lasting 7 seconds. Figure 4 illustrates the maximum distance traveled by the robot at each measured frequency pair.

Figure 5 shows the variation in distances between trials when sweeping through frequencies for motor 1 while keeping the other two motor frequencies fixed at 2.1V and 0V respectively (corresponding to the the bottom row of the heat map).

Combined, these results hint at the complexity of the underlying space of distances achievable by the full range of three motor voltages: even when only using two of the three motors, there is significant variation in distances traveled, and there is a non-linear relationship between motor frequencies and distance traveled. Lacking any analytical approach to mapping motor frequencies to corresponding gaits, this suggests that automated trial and error via hill climbing or genetic algorithm might be the best way to discover effective gaits.

## Three-Motor Gaits

Having demonstrated the diversity and complexity of two-motor gaits, we then manually explored three-motor gaits, searching for frequency sets which led to interesting and effective behaviors. We were able to discover sets which produced consistent clockwise, anti-clockwise, and linear locomotion.

Figure 7 illustrates the motion of the tensegrity over the course of 6 seconds of motion, at two-second intervals.

Maximum linear locomotion speed was on the order of 4cm/sec, or 2.4m/min. On an absolute basis this is four times faster than Paul's robot and half the speed of Kuizumi's. When normalized to body size, however, our tensegrity is considerably faster, while using simpler means of locomotion.

Videos of these gaits are available at the corresponding author's web page.

## Controllable Motion

Most compellingly, these frequency sets which result in diverse gaits can be sequenced in order to *steer* the tensegrity in a controllable fashion. Since one gait can be used to propel the robot forward, and a second to rotate it, these gaits can be sequenced in order to produce controllable motion.

Figure 7: Video frames, taken at two-second intervals, illustrating motion of the vibrating tensegrity. Given a single set of motor frequencies, the robot is able to exploit its vibrational tendencies in order to move quite quickly – at speeds over 4cm/sec. Videos available on the author’s web site.

To demonstrate this we created an alternating sequence of forward-propagating and rotational gaits which caused the tensegrity robot to traverse a path within the arena. A video of this trajectory is provided on our web page.

This method of steering a tensegrity robot simply by changing its mode of vibration is unique, and a valuable example of how adding morphological complexity can sometimes simplify the task of control, allowing aspects of control to be “outsourced” into the complex mechanics of a structure. This is, therefore, a valuable example of *morphological computation* in a tensegrity robot.

As we continue our studies, and scale to increasingly large and complex tensegrity robots, we hope to uncover an even more diverse range of gait behaviors, leading to more interesting and effective means of controlled locomotion.

## Discussion

There are several improvements we would like to make to move the system forward. Foremost among them is automating the discovery of effective motor frequencies with a physically embodied evolutionary algorithm, following in the footsteps of Harvey *et al.* at Sussex (Harvey *et al.*, 1997), Watson *et al.* (Watson *et al.*, 1999), and more recently Zykov (2004) and Yosinski (2011).

Like all physically embodied evolutionary robotics, however, we must deal with the issue of noisy evaluation, reliability, and consistency between trials. Some solutions lie at the algorithmic level (for instance, via multiple trials (Fitzpatrick and Grefenstette, 1988)), and some lie at the hardware level, for instance by using a more consistently smooth surface for evaluation. However, we want to avoid “sterile” surfaces – perfectly flat, perfectly smooth – since our ambition is to evolve robots capable of robust performance in rough and uncertain environments.

There is also the matter of the evolvability of the system itself. While the dynamics of tensegrities are complex enough to justify the use of automated optimization techniques (as opposed to analytical modeling) to generate gaits, our current control scheme is not very amenable to evolution. The use of a single control parameter (frequency) means that genotypes contain only three floating

Figure 8: *top*: A model of a larger 15-bar tensegrity, from (Rieffel *et al.*, 2010). *bottom*: a rig we have built to enable construction of the physical 15-bar tensegrity.

point loci, making the system somewhat too simple to explore with GAs. In the near term we are interested in more complex open-loop gaits, for instance, allowing each motor’s control voltage to change during a gait, and being able to specify its phase, amplitude, and frequency. In the longer term, we are interested in closed-loop control via Artificial Neural Networks (ANNs), with feedback provided by off-the-shelf micro-scale accelerometers (such as those used in smart phones).

We are also interested in using high speed video to analyze in more detail the varying resonant modes exhibited during different gaits.

Ultimately our goal is to build tensegrity robots with considerably more structural elements (while maintaining our relatively short strut length), such as the one shown in Figure 8. As tensegrities become more complex and irregular, they become increasingly difficult to analyze or model, fur-

ther necessitating our embodied approach.

## Conclusion

Tensegrities are an appealing platform for modern robotics. They are robust, agile, and can quickly change shape, lending themselves to promising applications ranging from urban search-and-rescue to biomedical devices. However, these properties also make them exceedingly difficult to control through conventional means, particularly as the complexity of the robot increases. We have described a means of actuating and controlling tensegrity robots which treats their dynamical complexity as a feature to be exploited rather than as a liability to be suppressed. By designing the structure in order to maximize resonant possibilities, we can make the robot move simply by vibrating it at specific frequencies. This leads to a tensegrity robot which is much smaller and much simpler than existing designs, and yet outperforms in many regards.

More valuably, we have demonstrated how we can affect behavioral change merely by changing the frequencies at which our robot vibrates. Achieving behavioral diversity by exploiting mechanical complexity in this manner is a valuable example of *morphological computation*, in which increasing dynamical coupling can, paradoxically, reduce the cost of control. Given the pervasiveness of both tensegrity and dynamical coupling in biological systems, our hope is that this can lead to a deeper understanding of how mechanically complex living systems at all scales of life move and interact with the world.

## Acknowledgments

The authors would like to thank RJ Hojnacki, Steve Stangle, and Julian Jocque, all of whom assisted in this research as part of undergraduate practica at Union College. Funding for undergraduate summer research by authors Mark Khazanov and Ben Humphreys was provided through the generosity of the Union College Summer Research Fellowship Program. Materials were paid for in part by several Union College Internal Education Fund (IEF) grants to the authors.

## Abstract

The evolution of naturalistic, embodied agents and behaviours has been a long-standing goal of Artificial Life since the initial, impressive work of Karl Sims. Incremental evolution has been used extensively to improve the quality of evolutionary search in many complex, non-linear problem spaces. This work sets out to disambiguate the lexicon around incremental evolution, advocating the term *environmental complexification* to represent the complexification of the problem domain. We then go on to analyse various complexification strategies in a structured, complexifiable and yet simple environment: a 3D agent-based obstacle task. We divide the strategies conceptually into *homogeneous* and *heterogeneous*; homogeneous strategies expose successive generations of the population to a single or tightly clustered range of objective functions while heterogeneous strategies present many, covering the range of complexity. It was found that widely-used homogeneous complexification techniques, for example direct presentation of difficult tasks or linearly-increased difficulty, fail due to either loss-of-gradient or temporally-local over-fitting (analogous to *catastrophic forgetting* in neural systems). Heterogeneous methods of complexification (including oscillatory strategies) that eliminate these issues are devised and tested. The heterogeneous category outperforms the homogeneous in all metrics, establishing a much more robust approach to the evolution of naturalistic embodied agents.

## Introduction

The evolution of naturalistic, embodied agents and behaviours has been a long-standing goal of Artificial Life since the initial, impressive work of Karl Sims. We are interested in evolving generalised behaviours rather than those that succeed in only a specific or narrow range of parameters: for example in agents able to climb over arbitrary obstacles rather than just those of a specific (maximal or other) height. It may appear desirable to evaluate each individual in each generation on all combinations of parameters for all behaviours, but this approach is infeasible as the number of combinations scales exponentially. We are therefore interested in evolutionary approaches in which each agent is evaluated on a small subset of parameters, in this paper on a single value for a single behaviour, and yet result in agents able to

perform over the full range of parameters, for example by having evolved generalised behaviours rather than ones that work only in a specific or narrow range of parameters.

Incremental evolution has been used extensively to improve the quality of evolutionary search in many complex, non-linear problem spaces. This work sets out to disambiguate the lexicon around incremental evolution, advocating the term *environmental complexification* to represent the complexification of the problem domain as described above. We then seek to identify and objectively compare the strengths and weaknesses of homogeneous and heterogeneous strategies for complexification of a problem domain when using incremental evolution. In homogeneous complexification strategies, for any short sequence of successive generations the population is exposed to a single or tightly clustered range of objective functions, while heterogeneous strategies present many, covering a range of complexity.

**Incremental Learning in Evolutionary Systems** Inman Harvey's SAGA paradigm, motivated by evolution in the natural world, set the stage for the computational use of incremental evolution by providing an evolutionary mechanism which allows an evolving species to maintain, at least theoretically, most if not all evolutionary pathways as potential candidates for exploration, no matter how converged the population has become to a single point in genotype space (Harvey, 1992, 1997). Once a SAGA algorithm is implemented, objective functions can be changed and the population can be expected to adapt to its new circumstances by traversing *neutral networks* in genotype space (Harvey, 1997, 2001). The requirements for the successful implementation of a SAGA-type incremental process are straightforward: inclusion of mutation as a genetic operator, smooth fitness landscapes and a redundant (high-dimensional) genotype to phenotype mapping which permits neutral networks - interconnected regions of equivalent fitness - to percolate through genotype space. Note that the term *incremental evolution* is used in a sense which implies continued change, development or acquisition of domain knowledge by the algorithm over time. Where there is a gradual increase in difficulty of objective function, we prefer the term *environmental com-*

*plexification* as mentioned in (Mouret and Doncieux, 2009). The label *incremental evolution* is also applied where intermediate solutions are moved to a new objective domain; this case we also consider a flavour of environmental complexification, a point we explain in more detail below.

Some of the earliest work which uses the environmental complexification approach directly is that of Gomez who (in addition to discrete, staged evolution over subtasks) gradually increased the speed of prey in a pursuit-avoidance simulation where neural networks were evolved to control simulated predators (Gomez and Miikkulainen, 1997). This work showed a very large performance gain by using the incremental approach. The work also identified an interesting adaptive approach where complexification is dependent upon agent performance at the current level of complexity. Mouret introduced a more general approach to rewarding sub-task performance than the hand-designed staged approach common until this point (Mouret and Doncieux, 2009). Complex agent behaviour was evolved incrementally in a two-dimensional task in (Robinson et al., 2007) where agents in a discrete world were trained to navigate a hostile environment and ultimately build a strategy for crossing an impassable obstacle. Environmental complexification was used to evolve swarm robots in (Kadota et al., 2012), although the complexification chosen constituted arbitrary, discontinuous changes to the agents' environment and not a smooth transition over a range of difficulties. Notwithstanding, once again the incremental approach delivered a much higher rate of success in the given task (co-operatively foraging for food in a two-dimensional environment). Oh et al. evolved controllers for unmanned aerial vehicles first using a non-incremental strategy. This strategy was found to perform badly as more constraints were added into the objective function so an incremental, task-subdivision strategy was used instead (Oh and Suk, 2013).

### Categorisation of Incremental Learning Techniques

Barlow identified two classes of incremental training schemes: functional incremental evolution and environmental incremental evolution (Barlow et al., 2004). In this definition, functional approaches parameterise fitness functions to increase the apparent difficulty of tasks toward the desired level of complexity whereas environmental approaches modify the environment around the evolving individuals without modifying the fitness function, with the same effect. Sub-categories of incremental evolution identified by Mouret in (Mouret and Doncieux, 2009) are *staged evolution*, *environmental complexification*, *fitness shaping* and *behavioural decomposition*. The most striking of these distinctions, common to both Barlow's and Mouret's work is environmental complexification; this category is of particular interest as semantically it can encompass all of the other categories identified and thus becomes synonymous with the sense of incremental evolution where the problem

is simplified and made progressively more difficult. Additionally, environmental complexification is the only category which adequately encompasses co-evolutionary systems (which can be seen as auto-complexification) which in turn are the natural precursor to open-ended evolutionary systems, the search for which is an active area of research in the Artificial Life domain.

**Incremental Learning in Neural Systems** The idea of incremental learning is not confined to evolutionary adaptive algorithms; neural network research has also considered this both as a problem (learning invariances piecewise) and as a solution (tackling complex problems) for networks generally, outside of any particular training scheme. In the standard approach of using neural networks, training and application are distinct phases: all training data are presented to the network and the system learns the invariances and abstractions in that data using some learning algorithm. Then, this trained network is put to work on unseen data. This method of presentation can make it difficult for the network to adapt to new, unseen data at a later time and cause networks to suffer the phenomenon of *catastrophic forgetting* (McCloskey and Cohen, 1989). In contrast to this, incremental learning algorithms are designed to allow the neural system to continually adapt to new information whilst maximising the information available in the network from previous training. This is an important concept for real world applications as often data is not available all at once and sometimes learning guides further exploration, meaning that learning is a continuous process rather than a discrete activity (Giraud-Carrier, 2000). One popular solution to the catastrophic interference problem found in these incremental learning schemes is to *rehearse* either already known data or pseudo-data representing the knowledge already in the network, interleaved with training on new information. See (French, 1999) for an overview and e.g. (Guajardo et al., 2010) for recent work using this technique.

**Complexification Strategies** As noted above, previous work has successfully leveraged the power of incremental evolution through successive increases in environmental complexity. However, attention has been focused solely on the outcome and the particular strategies used to complexify the environment have not been examined in detail. We assert that a rigorous theoretical underpinning of complexification is necessary both for the practical application of incremental evolution and the further elucidation of the interplay of agent and environment in co-evolutionary settings which ultimately lead to unbounded evolutionary activity.

The naive strategy presents the most difficult task to the evolving species at every opportunity. This *straw man* is unlikely to be successful: it was the failing of this approach that spurred the development of alternative, progressive strategies, e.g. linear increase in difficulty as time passes.

The linear approach has been used often to circumvent the bootstrapping problem, one of the first attempts occurring in (Gomez and Miikkulainen, 1997). This approach is a natural extension of human learning - start easy and then get harder - and the simplicity of implementation and broadness of potential application strengthen its appeal. Many task decomposition strategies can also really be considered an implementation of a linear increase in complexity, albeit discrete rather than continuous. Gomez also proposed an extension to the linear increase in task complexity where difficulty is only increased when the evolving species achieves a certain level of performance against the current objective function. This interesting strategy has not been developed in detail by others but we consider it a good candidate for analysis as it enforces gradient at every level of difficulty, potentially solving some or all of the issues described in the introduction to this work.

Although not often described in previous work, random presentation of different task complexities may also be useful and finally, drawing upon the ideas of incremental learning in neural systems we propose a strategy of repeated presentation of earlier, simpler tasks in an evolutionary setting. These strategies may have something to offer beyond linear or adaptive monotonic changes in task complexity.

## Hypotheses

We anticipate that homogeneous complexification strategies, for example direct presentation of difficult tasks or linearly-increased complexity, will perform poorly due to either loss-of-gradient or temporally-local over-fitting (analogous to *catastrophic forgetting* in neural systems). Heterogeneous strategies are our proposed approach to overcoming forgetting, as an analogue of rehearsal, with smoothly changing heterogeneous strategies, such as oscillatory strategies, also overcoming the loss-of-gradient problem. For oscillatory strategies, the current range of difficulties is from zero to the amplitude of oscillation. A gradual increase of this range may be expected to show improved performance. At very low frequencies, such a strategy would degenerate to the homogeneous linear strategy, and at very high frequencies to the random strategy. Thus, we propose the following hypotheses:

H1: Homogeneous strategies will fail to achieve good coverage on the evaluation task.

H2: Heterogeneous strategies (with the possible exception of random) will achieve better coverage than homogeneous strategies.

H3: Heterogeneous strategies with a range of difficulties increasing over time will outperform heterogeneous strategies with constant range.

H4: A heterogeneous strategy using an oscillatory approach, as an analogue of rehearsal, will exhibit an optimal frequency for any particular problem.

## Method

The general setup of our experiment is designed to test the above hypotheses in a task which provides a smooth fitness landscape and neutrality in genotype space. We have chosen the evolution of controllers for three-dimensional agents as the platform, tasked with learning how to walk and climb over an obstacle. The height of the obstacle represents the ‘complexification’ parameter of the system; task difficulty varies somewhat as obstacle height varies but the ultimate objective for the agents is to deal with every possible obstacle - this is the most complex case. Thus, we can assess which of many possible complexification strategies (that is presentation of tasks of various difficulties) provide the strongest gradient for the evolutionary system to climb and the most robust final evolved agents.

**A. The Physical Model** In the tradition founded by (Sims, 1994) and continued by many others, we perform all experiments on agents in a three-dimensional virtual world consisting of collidable rigid bodies connected by powered constraints. Unlike Sims, our morphology is a fixed quadruped which is controlled by a feed-forward three-layer perceptron augmented by sinusoidal input. The cuboid quadruped torso (length 0.4m) is supported by four limbs, each comprising an upper and lower portion (length 0.2m). Constraints with two degrees of freedom limit the motion of torso and upper limb at the hips; constraints with one degree of freedom limit the motions of lower limb and upper limb at the knee. (See figure 1 for a visual representation.) The range of motion in each case is limited to  $\pi$  radians centred on the diagonals extending from the centre of the agent to the lower corners, also the points of attachment for each limb. The maximum power that can be applied at any constraint is a force of  $\pm 0.1N$ . The obstacle is situated 1m from the agent’s origin and extends to infinity in  $x$  and for 0.02m in  $y$ . The height of the obstacle is varied as described elsewhere. The physical simulator used was ODE 0.12, using double-precision arithmetic, the standard big-matrix step function and a step-size of 0.02s. Coulomb friction was applied at contacts between the agent, the obstacle and the ground plane with  $\mu = +\infty$ .

**B. The Control System** The agent controller is modelled by a standard three-layer feed-forward neural network with 12 hidden nodes. Networks receive 4 real-valued inputs in addition to 12 joint-angle sensors. Inputs comprise two sinusoidal oscillators (sine and cosine, period 1 second), an input describing the target location in relation to agent position and orientation (difference between distance from target to each ear, divided by distance between ears) and an up-sensor which describes the orientation of the agent’s head relative to the ground plane. Network updates are made synchronously with physics integration. Each hidden node activation is a weighted sum of its inputs with a hyperbolic tan activation. Each output node activation is a weighted sum of hidden nodes with a logistic activation function.

Figure 1: Visualisation of physical environment. Agent, obstacle and target location are shown.

**C. The Evolutionary Algorithm** Individual genotypes specify floating-point weights for the neural control system. Initial values for the first generation are drawn from a uniform distribution  $x \in [-1, 1]$ . In each run, the evolutionary simulation is progressed for 5000 generations using a population of 50 individuals. Individuals are evaluated for 20 simulated seconds and the objective function is defined as the total distance covered in the x-y plane toward a target position situated on the other side of the obstacle. At each new generation, individuals are scored according to the objective function and ranked in order of fitness. The lower half of the population is replaced with mutated, crossed-over variants of the upper half. Mutation occurs on average twice per genotype and consists of adding a value drawn from a Gaussian distribution with  $\sigma = 1$  and  $\mu = 0$ . Single-point crossover is implemented at a random point on the genotype and crosses the current parent individual with another random individual from the best half of the population (possibly itself.)

**D. The Experimental Setup** Sixteen possible strategies for environmental complexification have been identified and tested; each of these strategies modifies the height of the obstacle in the environment for the current generation of the species. In every case the maximum height of the obstacle,  $\tau$  is 0.1m. Height function  $h$  for generation  $G$  and wavelength  $\lambda$  is defined for each strategy as follows:

1. Direct presentation of environment with complexity  $\tau$  at every generation:  $h(G) = \tau$  (Strategy 1)
2. Presentation of a randomly complex environment at each generation, with complexity drawn from a uniform distribution between 0 and  $\tau$ :  $h(G) = \text{random}(0, \tau)$  (Strategy 2)

3. Gradual complexification of the environment, with complexity interpolated linearly between 0 and  $\tau$  from generation 0 to generation 4000 and fixed at  $\tau$  from generation 4001 to 5000 (Strategy 7):

$$h(G) = \begin{cases} \frac{\tau G}{4000}, & G < 4000, \\ \tau & \text{otherwise} \end{cases}$$

4. Oscillating complexification of the environment ( $\lambda = 50, 100, 200, 400$  generations), with complexity following a sinusoidal increase and decrease over wavelength  $\lambda$  with maximum amplitude  $\tau$  (Strategies 3, 4, 5 and 6):

$$h(G, \lambda) = \tau \frac{1 + \sin(\frac{2\pi G}{\lambda} - \frac{\pi}{2})}{2}$$

5. Oscillating complexification of the environment as above, with maximum amplitude interpolated linearly between 0 and  $\tau$  from generation 0 to generation 4000 and fixed at  $\tau$  from generation 4001 to 5000 (Strategies 8, 9, 10 and 11):

$$h(G, \lambda) = \begin{cases} \frac{\tau G}{4000} \frac{1 + \sin(\frac{2\pi G}{\lambda} - \frac{\pi}{2})}{2}, & G < 4000, \\ \tau \frac{1 + \sin(\frac{2\pi G}{\lambda} - \frac{\pi}{2})}{2} & \text{otherwise} \end{cases}$$

6. Adaptive modification of 1, where  $\tau$  is increased by 1% when the average fitness of the population has increased or remained the same and decreased by 1% if average fitness has decreased. (Strategy 12)
7. Adaptive modification of 5 where  $\tau$  is increased by 1% when the average fitness of the population has increased or remained the same and decreased by 1% if average fitness has decreased. (Strategies 13, 14, 15 and 16).

## Results

Table 1 shows that *no homogeneous complexification strategy (direct, linear or adaptive) was able to achieve success on all task difficulties*, in any experimental run. In contrast, *all heterogeneous strategies did*. The adaptive oscillating ( $\lambda=50$ ) strategy achieved 100% success in 20% of runs and 95% success in 48% of runs.

Figure 2 shows a complete view for each strategy, with  $\lambda=50$  selected for each oscillating strategy and each strategy's 100 runs sorted along the horizontal axis by proportion of successful evaluations (shown on the vertical axis). Note that we are primarily interested in the upper portion of this graph, that is in those populations able to complete the task at most obstacle heights). The adaptive strategy generated fewer populations than the linear strategy, successful on fewer than 50% of evaluations (over the full range of obstacle heights) but of greater interest is that it generated only a comparable number of populations successful on more than 90% of evaluations. The random strategy, whilst better than all homogeneous strategies, is

Figure 2: Performance of various strategies, 100 runs per strategy sorted best to worst.

| Number                   | Strategy                                 | % runs with success of at least: |      |

Table 2: Significance table showing one-tailed statistical relationship between strategies,  $p < 0.05$ . Arrows indicate statistical dominance of one strategy over another (significantly higher median value). Statistical test used was the Mann-Whitney U-test.

by far the worst method of the heterogeneous strategies. In turn, the simple oscillating strategy is outperformed by the increasing oscillating and adaptive oscillating strategies.

Figure 3 shows a box plot of successful evaluations (%) for each strategy (with whiskers to 1.5 interquartile ranges below and above the lower and upper quartiles), complete with a range of wavelengths (50, 100, 200 and 400 generations). Mann-Whitney U tests were performed to examine significant differences in median number of evaluative successes between strategies and within strategies (by varying wavelength). In table 2, a left arrow indicates that the strategy corresponding to the row number has a significantly higher ( $p < 0.05$ ) median success rate than the strategy corresponding to the column number (and an up arrow vice versa), shown particularly clearly by strategies 8 and 13. Within each of the increasing and adaptive oscillating strategies, the median number of successful evaluations was found to be significantly higher ( $p < 0.05$ ) for strategies with wavelengths of 50 to 100 generations when compared to the same strategy with four times the wavelength or higher. Within the simple oscillating strategy, the long wavelength (400 generations) produced a significantly lower median ( $p < 0.05$ ) than shorter wavelengths (50, 100, 200 generations).

Strategies which oscillate showed the best performance. We found no significant difference in median between the increasing and adaptive oscillating strategies at equal wavelengths. We found that either a linear or an adaptive increase in maximum amplitude over the training time performed significantly better than simple oscillation. For both increasing oscillating and adaptive oscillating the two lower

wavelengths (50 and 100 generations) showed a significantly higher ( $p < 0.05$ ) median number of successful evaluations than the simple oscillating strategies at all wavelengths.

On average, the adaptive strategy performed significantly better than the direct, linear and random strategies, and significantly worse than every oscillatory strategy (except the simple oscillating strategy at wavelength 400 for which we found no significant difference).

The linear strategy resulted in a significantly higher median number of successful evaluations than the direct and random strategies (even though the random strategy produced more highly fit populations from many more runs) and a significantly lower median than all other strategies.

On average, the random strategy performed significantly worse than all other strategies except for the direct method, which was significantly worse than all other strategies.

In order to determine whether the poor results of the linear strategy is due to either evolutionary loss or failure to gain we determined the proportion of successful evaluations at each obstacle height throughout the evolutionary progress, for each strategy. Figure 4 shows that all strategies achieved 8% success at all obstacle heights, with the exceptions of direct (for which obstacle height is always 100%) and adaptive (low coverage at high obstacle height). The linear strategy achieved more successful evaluations than the simple oscillating strategy at all wavelengths during the evolutionary phase, indicating that its ultimate failure is due to evolutionary loss rather than a failure to gain. Only 10% of the final population from linear runs were able to walk to the target with no obstacle, compared to at least 69% for the increasing and adaptive oscillating strategies. As in figure 3, figure 5 shows the number of successful evaluations for each strategy but drawn only from those runs able to reach the target with no obstacle (that is eliminating those runs which experienced the greatest evolutionary loss), and shows that in these cases, linear performance has a range comparable to the simple oscillatory strategies and a median comparable to the increasing and adaptive oscillating strategies.

To investigate the dependency of success rate on oscillatory frequency we evaluated the simple, increasing and adaptive oscillating strategies across as range of wavelengths from 2 to 10000 generations; figure 6 demonstrates this relationship. As wavelength approaches zero, the proportion of successful evaluations approaches that of random. As wavelength approaches total evolutionary time (number of generations), the proportion of successful evaluations approaches that of linear. Between these points, it can be seen that for each strategy there is an optimal wavelength (for the current algorithm, around 50-100 generations).

## Discussion

It is clear from the results presented above that there is a strong distinction between the homogeneous and heterogeneous strategies. No homogeneous strategy achieved 100%

Figure 4: Strategy performance against obstacle height during evolution.

Figure 5: Success rate over all obstacle heights for various strategies (only aggregates runs which solved the task at zero-height). (See Table 1 for description of numerical labels; order preserved from Figure 3.)

Figure 6: Strategy performance (% success) against wavelength for oscillating strategies.

coverage of the evaluation task in any run (Table 1) whereas all heterogeneous strategies did. Within the homogeneous category, the trivial, direct method of presentation was by far the least successful (Figures 2 and 3). The linear strategy was more successful but the best strategy in this category was the adaptive strategy. The poor performance of the homogeneous category can be explained by *evolutionary forgetting*: these strategies have either lost evolutionary gradient and drifted away from any early successes (linear) or over-specialised on later parts of the problem (adaptive).

The heterogeneous strategies perform better than the homogeneous group: the most successful strategies we explored all made multiple presentations of easier tasks at later stages of the evolutionary run, at the expense of fewer presentations of later tasks. These strategies all performed well at the hardest task and had the best generalisation performance over the whole range of tasks, suggesting that our hypothesis has merit.

The random strategy is the least successful strategy in this category. This may be due to the same problem of gradient loss as in the homogeneous group. As found in the homogeneous group, the linear and adaptive modifications of the oscillating strategy showed the best performance of all; the slow increase in task difficulty maintains a strong evolutionary gradient and the cyclical nature of task presentation consolidates earlier gains and causes the evolving population to prefer generalised solutions abstracted over the whole problem domain.

This consolidation is dependent on the frequency of representation of earlier, or easier, parts of the task. When investigating this frequency, it can be seen that a clear optimum exists in the frequency domain where cyclical strategies are able to maximise this consolidation without losing gradient. This optimum is likely to be problem-specific and a range of values should be explored for any given task. However, in the limit of wavelength, i.e. at very low and very high frequencies, it can be seen that the performance of the evolving populations begins to approximate, for low and high frequencies respectively, the linear and random strategies. This offers an abstract insight into the underlying mechanism at work - the maintenance of selective pressure and whole-task capability. As these components reduce in effectiveness due to the change in wavelength, so the evolving populations degenerate into the simpler strategies described above. The successful cases are those where environmental change is fast enough to induce a generalisation in the agent's approach to the task but slow enough to prevent catastrophic loss of gradient when evaluating partial solutions.

## Conclusions

The points made in the discussion section support our hypotheses. The homogeneous strategies showed weak performance on the evaluation task, with no strategy achiev-

ing full coverage in any run. Conversely the heterogeneous strategies, including surprisingly the random strategy, all achieved full coverage in some runs. Those heterogeneous strategies with a range of difficulties increasing over time (increasing and adaptive oscillating) outperformed the simple (constant range) oscillating strategies, showing a much higher proportion of successful runs. Finally, we demonstrated that oscillating strategies do exhibit an optimal frequency.

Complexification strategies for incremental evolution offer a powerful mechanism for adaptive problem solving. However, this power comes at a price: it is easy to lose information learned earlier in the process. In order to fully exploit this power appropriate complexification strategies have to be realised in order to drive populations along desirable adaptive pathways. There are many options for formulating these strategies: much previous work has involved, in one manner or another, a simplification of the objective function and then a progressive complexification as time passes. In this work we found that many strategies encounter loss-of-gradient or over-fitting problems. We present a solution in the form of heterogeneous complexification strategies which combine solutions to those problems to deliver robust populations. Our approach can be translated to many scenarios where progressive complexification is used to guide an incremental evolutionary process; further exploration of the limitations and advantages of heterogeneous complexification within different problem domains would be useful in order to generalise these conclusions. Additionally, the oscillating strategies exhibited an optimal wavelength for representation. It is unclear whether this optimum is task-dependent or whether there is an underlying principle and optimal wavelength for this type of training; this question also merits further work.

Finally, we would advise that in general while a random presentation of subtasks or objective difficulty levels is preferable to a linear increase, as a minimum guideline an increasing heterogeneous complexification strategy should be used. This rehearsive, cyclical approach to presentation not only maintains evolutionary gradients but also promotes generalisation amongst the evolving populations from subtask-specific adaptation to performance across the super-task.

# Conformity and Nonconformity in Collective Robotics: A Case Study

Gregory Vorobyev\*, Andrew Vardy, and Wolfgang Banzhaf

## Abstract

In this work, we develop a social behavioral model designed for multi-agent systems for solving the collective sorting task. Experiments show that under this model agents are capable of improving their performance significantly and can achieve better results than conventional swarms of agents lacking communication and social abilities.

## Introduction

In his fascinating book “The Social Animal”, Elliot Aronson defines conformity “as a change in a person’s behavior or opinions as a result of real or imagined pressure from a person or group of people” (Aronson, 2007). Conformity is one of the essential and most important aspects of human society. Failure to conform to the rules issued by society may turn out to be not only merely inconvenient, but even dangerous. Driving down the wrong side of the street can be an example of a nonconformist behavior that will most likely lead to tragic consequences (Aronson, 2007). Nonconformity, however, often works to the long-term benefit of the society as a whole. One example of “useful” nonconformity could be a scientist attempting to look at a well-known problem from an entirely new angle, which can be controversial to the viewpoint generally accepted. Sometimes this could result in a revolution in science (i.e., consider Einstein’s theory of relativity vs. classical Newtonian mechanics).

In this paper, we develop a simple model of conformity and nonconformity in an artificial society. This model is not intended to be a valid counterpart of the relevant phenomena in the human society. Rather, our aim is to attempt to incorporate some degree of *social intelligence* (specifically, the ability to choose between conformity and nonconformity in behavior) in artificial agents and to study whether this additional “social” part of agent reasoning could be beneficial in terms of the performance on the task being executed.

As a case study, we use the sorting task in the context of multi-agent systems, which is formulated as follows: given a set of objects of different types  $\{x_1, x_2, \dots, x_n\}$ , the group of  $N$  agents is to collect them into homogeneous clusters. *Swarm robotics* offers distributed algorithms for solving this

problem (Bonabeau et al., 1999; Deneubourg et al., 1991; Bayindir and Sahin, 2007; Beckers and Holland, 1994; Melhuish and Hoddell, 1998; Wang and Zhang, 2004; Verret et al., 2004; Vorobyev et al., 2012). The distinguishing property of the swarm-based approach is that agents operate and perceive only locally; thus, no global supervision and/or knowledge is required. While swarm-based algorithms typically show slower convergence than centrally-controlled approaches, their advantages are simplicity, flexibility and robustness (Sahin, 2005). A swarm agent has very limited sensing capabilities. As it is highlighted in the next section, the only input to one popular swarm-based sorting algorithm by (Deneubourg et al., 1991) is  $f(x)$ , which roughly estimates the density of objects of type  $x$  in the immediate neighborhood. To obtain  $f$ , an agent only needs a sensor which allows to recognize the type of an object, if there is any, right in front of the agent. In many contributions in this field, agents are even not aware of each other; i.e., *kin recognition* is not present (Bayindir and Sahin, 2007). Such “social ignorance” is viewed as beneficial, because it guarantees scalability and robustness of the approach.

This work primarily concentrates on extending Deneubourg et. al.’s sorting algorithm by introducing additional input information. We refer to this information as *social*, because it represents knowledge about the goals of other agents. Obtaining this new type of information will require explicit communication, as opposed to implicit communication, commonly employed by robotic swarms (e.g., through *stigmergy* (Beckers and Holland, 1994)). Since it is generally accepted that communication capabilities in swarm-based systems should be kept as minimal as possible, we also refer to the group of our “socially intelligent” agents as a *society* as opposed to a *swarm*. This work offers some evidence that socially aware agents could perform more effectively and “intelligently” than their swarm counterparts. The term *social intelligence*, as well as *artificial social intelligence* are probably too broad to cover in one paper; rather, we concentrate on just one social phenomenon – conformity and nonconformity. Much like traditional swarm robotics is inspired by social insects (see,

e.g., (Bonabeau et al., 1999)), we are inspired by arguably the most successful social beings we know – humans.

Although sharing information between agents as such is not new in the field of collective and swarm robotics, most of the contributions that employ this concept tend to focus on extending individual's sensory capabilities by accessing perception, or memory, of others (Verret et al., 2004; Grech et al., 2012). For example, in the collective clustering task, agents can share information about the clusters they have seen, and perform different actions based on that information; in some sense, this would be equivalent to having non-communicating agents with enhanced sensing capabilities (e.g., increased sight range). In contrast, this paper studies how agents with limited sensing capabilities make decisions based purely on the number of other agents that made a similar (or different) decision. *Conformist* agents always tend to make decisions that are similar to the course of the majority, whereas *nonconformist* agents are more independent. In some sense, our agents resemble *zero-intelligent* particles described in (Bentley and Ormerod, 2011).

One important assumption made in this paper, in addition to the ability of agents to distinguish objects of different types and to explicitly communicate with each other, is that they can remember *home locations* in the environment to which they can return if they wish so. This assumption is, in fact, biologically plausible. For example, honeybees can travel long distances and return to their hives (Seeley, 2010). We are not concerned with the details of the implementation of a homing mechanism; rather, we just assume that our agents can store their home locations in their *local coordinate system*. This information will further be subject to social exchanges.

The next section describes the sorting algorithm followed by socially intelligent agents. We then present experimental results, a comparison with Deneubourg et. al.'s "socially ignorant" agents, and the analysis of different parameters of the social model.

## The model

The proposed "social" algorithm is derived from Deneubourg et. al.'s model, first introduced in 1991 (Deneubourg et al., 1991) (which from now on is referred to as "Ant-Like Robots", or "ALR", model). The behavior of ALR agents can be summarized as follows. Each agent moves randomly. If an agent who is not carrying an object encounters an object of type  $x$ , it decides whether or not to pick it up. The probability  $p_p(x)$  of doing so is defined as follows:

$$p_p(x) = \left( \frac{k_p}{k_p + f(x)} \right)^2 \quad (1)$$

where  $p_p(x)$  is the probability to pick up the object of type  $x$ ,  $0 \leq f(x) \leq 1$  is a function estimating the relative density

of objects of type  $x$  in the current neighborhood, and  $k_p$  is an arbitrary constant. Each agent has a short-term memory  $m$  of size  $N_m$  for storing the information of what kind of objects (if any) it has encountered in the recent past.  $f(x)$  is calculated based on that memory:

$$f(x) = \frac{1}{N_m} \sum_{i=1}^{N_m} \begin{cases} 1, & \text{if } m_i \equiv x, \\ 0, & \text{otherwise.} \end{cases} \quad (2)$$

In a similar manner, the probability of depositing the object being carried upon encountering an empty cell is defined as follows:

$$p_d(x) = \left( \frac{f(x)}{k_d + f(x)} \right)^2 \quad (3)$$

where  $k_d$  is a constant. Thus,  $p_p(x)$  decreases with  $f(x)$  from 1 (when  $f(x) = 0$ ) to 0.25 (when  $f(x) = k_p$ ), and  $p_d(x)$  increases with  $f(x)$  from 0 (when  $f(x) = 0$ ) to 0.25 (when  $f(x) = k_d$ ).

## Home locations and division of labor

In the model described, agents pick up and put down objects as they walk randomly in the environment. The performance of the sorting task, however, can be significantly improved if each agent has a *home location*, that is, the location where the cluster of objects is to be formed. The algorithm can then be modified as follows. An agent starts looking for an object to pick up by roaming randomly. Upon encountering an object, the agent picks it up with probability  $p_p$ . The agent then deterministically returns to its home location. Once the home location is reached, the agent starts roaming randomly and tries to put down the object into any empty cell it finds with the probability  $p_d$ . When the object is deposited successfully, the agent starts looking for another object.

It is obvious that bringing objects of different types to the same home location will not solve the sorting problem. Thus, there must be only one type of object associated with each particular home location and hence with each agent. To be more general, from now on, we will refer to the object type as *task*; e.g., "agent  $A$  is executing task  $x$ " is equivalent to "agent  $A$  looks for objects of type  $x$  and brings them to its home location". The question is then how to assign tasks to agents (that is, how to configure *division of labor*). One simple solution (perhaps not optimal, but acceptable in our case) would be to assign a task to an agent according to the type of the very first object which that agent encounters at the beginning of the simulation. Another question is how to assign initial home locations to agents; in this paper, this assignment is uniformly random.

As it will be shown further, a group of agents employing the homing algorithm demonstrates better performance on average than randomly roaming ALR agents. It is obvious, however, that the homing approach itself has a significant drawback: it is not flexible. The assignment of tasks and

home locations to agents is fixed. Therefore, if none of the agents has been assigned to a task  $x$ , then objects of that type will be unaffected by the sorting process. On the other hand, if more than one agent have been assigned to task  $x$ , then convergence to a single cluster of type  $x$  will never be achieved (assuming that the home locations of  $x$ -agents are sufficiently far from each other). The situation is even worse if the number of agents is large, or the distribution of objects of different types is not uniform.

### Conformity and nonconformity

We propose to solve the problem of a fixed assignment of home locations and tasks by using explicit communication between agents. If two agents  $A$  and  $B$  are currently located within the communication range  $r$  of each other, they can share information about their home locations (denoted as  $h_A$  and  $h_B$ , respectively) and tasks (denoted as  $x_A$  and  $x_B$ ).

If both of them are working on the same task  $x$ , then they should agree on a single home location to guarantee convergence to a single cluster. In our model, the probability  $p(h_B \leftarrow h_A)$  of that  $h_A$  will convert to  $h_B$  is defined as follows:

$$p(h_B \leftarrow h_A) = \min \left[ 1, \left( \frac{|h_B|}{|h_A| + l_h} \right)^2 \right] \quad (4)$$

where  $0 \leq |h_X| \leq 1$  is the estimated proportion of other agents (excluding  $X$ ) that have their home locations at  $h_X$ , and  $l_h$  is a constant, which we interpret as *home loyalty*. Thus,  $p(h_B \leftarrow h_A)$  increases with  $|h_B|$  and decreases with  $|h_A|$ .

$|h_X|$  can be estimated as follows. Each agent  $A$  has a memory  $M$  containing information about other agents met (agents have unique identifiers associated with them). If a piece of that memory  $M_B$  contains information about some other agent  $B$ , then  $M_B^h$  will denote  $h_B$  at the time of the last conversation between  $A$  and  $B$ , and  $M_B^x$  will denote  $x_B$  at the same moment in time. Note that  $M_B^h$  at any given moment is not necessarily equal to the current  $h_B$ , because  $B$  might have changed its home position since the last time  $A$  and  $B$  communicated. Then  $A$  can estimate  $|h_X|$  using the following formula:

$$|h_X| = \frac{1}{|M|} \sum_{i=1}^{|M|} \begin{cases} 1, & \text{if } M_i^h \equiv h_X, \\ 0, & \text{otherwise.} \end{cases} \quad (5)$$

Note that  $M_i^h$  and  $h_X$  should be defined with respect to the same reference frame, for example, with the local coordinate system associated with  $A$ . Thus, whenever  $B$  informs  $A$  about its home location  $h_B$  defined with respect to  $B$ 's reference frame,  $A$  should transform this vector to  $A$ 's coordinate system. We assume that  $A$  is able to perform this operation by using the information about the location of  $B$  with respect to  $A$  at the time of communication.

If during a conversation  $A$  and  $B$  discover that they work on different tasks, there is a chance that one of them will convert to the other's task. The probability of doing so  $p(x_B \leftarrow x_A)$  is defined similar to that of converting to the other's home location, namely:

$$p(x_B \leftarrow x_A) = \min \left[ 1, \left( \frac{|x_B|}{|x_A| + l_x} \right)^2 \right] \quad (6)$$

where  $0 \leq |x_X| \leq 1$  is the estimation of the number of other agents (excluding  $X$ ) working on the same task as  $X$ , and  $l_x$  is a constant interpreted as *task loyalty*. Thus,  $p(x_B \leftarrow x_A)$  increases with  $|x_B|$  and decreases with  $|x_A|$ . For obvious reasons, upon switching to  $B$ 's task, agent  $A$  will also have to deterministically switch to  $B$ 's home location.

From Eq. 4 and Eq. 6 one can try to predict the dynamics of the reassignment of home locations and tasks. First of all, if there are originally  $N$  agents, each assigned to a unique task and a unique home position, then no conversions will occur, since  $|h_B|$  and  $|x_B|$  in those equations will always be zero. If, however, more than one agent are assigned to one task, then they will eventually "recruit" all other agents and converge to a single homogeneous cluster. If there are several groups of size more than 1 assigned to different tasks, all agents will still end up with the same task and the same home position as time continues indefinitely. We refer to the behavior of such agents as *conformity*, because it resembles the similar phenomenon in human society. The conformist behavior in our model can briefly be summarized as follows: "always follow the majority, both in terms of task and home location".

The idea behind conformity is *cooperation*. Agents should not pursue their own individual goals, which may interfere with each other; rather, they should work as a team. In this case, the team is an example of self-organization; the decision of where and what kind of clusters should be formed is collective and emergent. As experimental results show, conformity helps avoid conflicting goals, e.g., different home locations of the same object type. Conformity also helps improve the clustering performance of the objects of a given type  $x$ , because the number of agents involved in the process of clustering tends to increase up to  $N$ .

It is clear, however, that once agents have all converged to a single task, objects of other types will never become subject to sorting again. Thus, there must be a probability  $p_n$  for a conformist agent to give up its current task and home location and to switch its attention to objects of neglected types. This probability may be fixed. However, we suggest that it may be more reasonable to calculate it by estimating the *performance*  $u$  of the agent's work, e.g., how many useful actions the agent has accomplished within the last  $T_U$  steps. The only actions considered useful are picking up an object or putting it down. Random roaming in search for objects, direct routing to the home location, or random roaming in

search for empty cells to deposit an object are not considered useful actions. We could estimate the performance as follows:

$$u = \min \left( 1, \frac{n_u}{N_U} \right) \quad (7)$$

where  $n_u$  is the number of useful actions accomplished within the last  $T_U$  time steps, and  $N_U$  is the required maximum number of useful actions, at which  $u$  is saturated at 1. For example, we may assume that accomplishing  $N_U = 10$  useful actions within the last  $T_U = 500$  time steps should be considered ideal performance. Note that large values of  $n_u$  with respect to  $T_U$  will hardly be ever achieved, because generally agents spend much more time roaming randomly than picking up or putting down objects.

Having estimated  $u$ , we can calculate  $p_n$  using the following equation:

$$p_n = \left( \frac{1 - u}{1 - u + c} \right)^2 \quad (8)$$

where  $c$  is a constant which we refer to as *conformity threshold*. Thus,  $p_n$  decreases with  $u$  from  $\left( \frac{1}{1 + c} \right)^2$  (when  $u = 0$ ) to 0 (when  $u = 1$ ).

If agent  $A$  has decided to give up its current task  $x_A$  at its current home location  $h_A$ , it starts random walk for a period of time (in our experiments, this period is equal to 300 iterations). Once 300 iterations have passed, the current location of  $A$  becomes its new home location. The behavior of  $A$  is then completely identical to the behavior of the agent that has just started the simulation: that is,  $A$  starts random walk, and the first object met defines  $A$ 's new task  $x'_A$ .  $A$  then starts looking for  $x'$ -objects and brings them to  $h'_A$ .

Suppose that  $x'_A \equiv x_A$  and  $|h_A|$  is relatively large. Then it is likely that  $A$  will sooner or later encounter one of the agents still working at  $h_A$ . Since  $|h_A| > |h'_A|$ ,  $A$  will be likely to convert back to  $h_A$ . This mechanism prevents agents from starting a new cluster of the same type to which the group has previously converged to.

Suppose, however, that  $x'_A \neq x_A$ , and all agents but  $A$  are working on  $x_A$ . Then  $A$  upon encountering any of its former colleagues will be likely to convert back to  $x_A$  (because  $|x_A| > |x'_A|$ ). To prevent this, we consider  $A$  a *nonconformist*. In our model, a nonconformist, i.e., an agent that has recently given up the task carried out by the majority and started executing a new task, gains a special "ability" that allows it not only to keep executing its new task, but also to recruit other agents.

To distinguish formally  $A$  from other agents that are working within groups, we define a measure of *nonconformity*  $\psi$  associated with each agent.  $\psi_A = 1$ , as a reflection of the fact that  $A$  does not conform to the majority. For any agent  $X$  that works within a group,  $\psi_X = 0$ . We now update Eq. 6 taking into consideration nonconformity  $\psi$ :

Figure 1: A screenshot from the simulation taken shortly after a nonconformist appeared. Agents are depicted as squares, and objects to be sorted are drawn as smaller circles. There are three types of objects – red, blue, and green pucks. Yellow squares correspond to unladen agents, and blue squares denote agents that are carrying pucks. A magenta border around an agent  $X$  indicates that  $\psi_X > 0$ . For each agent, a white line is drawn to show the distance from its home location. In this experiment, there are 600 pucks (200 pucks of each color),  $N = 30$ , and the grid size is  $80 \times 60$ .

$$p(x_B \leftarrow x_A) = \begin{cases} \min \left[ 1, \frac{\psi_B}{\psi_A + l_c} \right], & \text{if } \psi_A > 0 \text{ or } \psi_B > 0 \\ \min \left[ 1, \left( \frac{|x_B|}{|x_A| + l_c} \right)^2 \right], & \text{if } \psi_A = \psi_B = 0 \end{cases} \quad (9)$$

where  $l_c$  is a constant which can be referred to as *loyalty to crowd*.

Thus, any agent  $A$  with positive nonconformity will have a zero probability of joining a conformist  $B$  (since  $\psi_B = 0$ ). Conformist  $B$ , however, will have a positive probability of joining nonconformist  $A$ :  $p(x_A \leftarrow x_B) = \frac{\psi_A}{l_c} > 0$ . If both  $A$  and  $B$  are conformists, Eq. 9 is reduced to Eq. 6.

The last detail is updating  $\psi$ . For conformists,  $\psi$  always remains zero. Once a conformist  $B$  has been recruited by a nonconformist  $A$ , it accepts its value of nonconformity:  $\psi_B = \psi_A$ . Furthermore, each nonconformist  $A$  decreases its nonconformity as the number of its colleagues increases:

$$\psi'_A = \begin{cases} 0, & \text{if } \psi_A = 0 \\ 1 - \min \left( 1, \frac{|h_A|}{N_G} \right), & \text{otherwise} \end{cases} \quad (10)$$

where  $N_G$  is the maximum size of a group that can be recruited by a nonconformist. Upon reaching this limit,  $A$

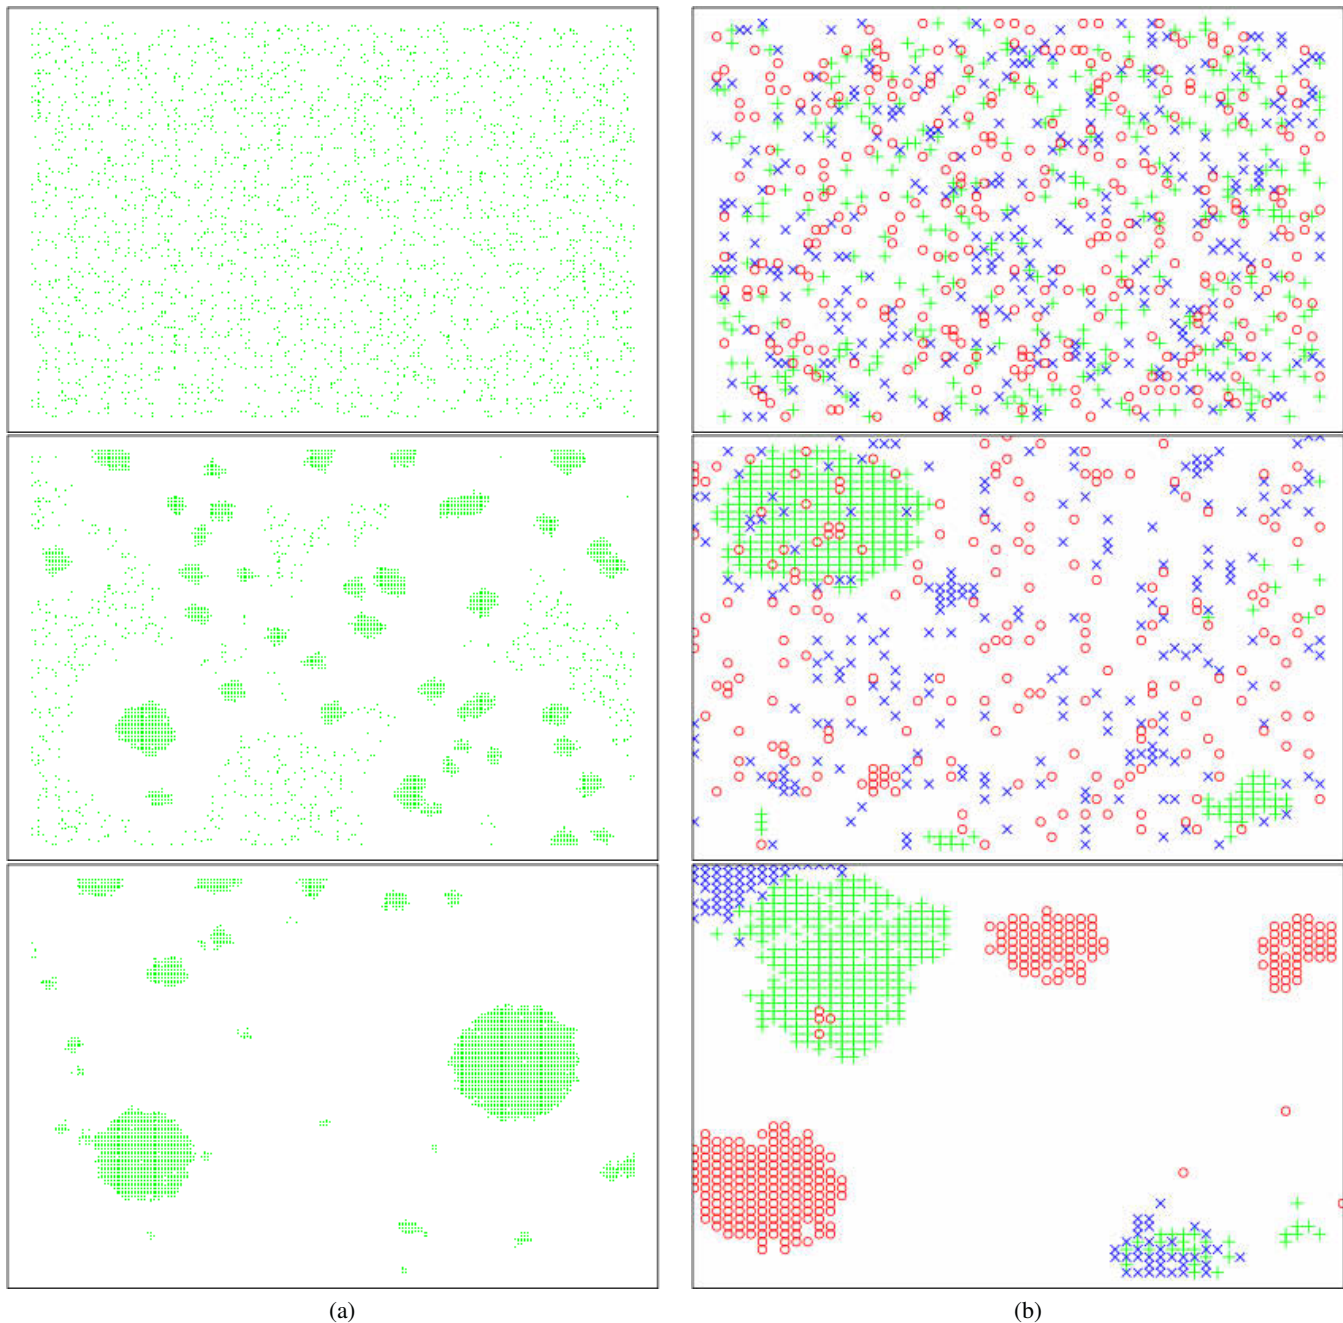

Figure 2: **(a)**: Clustering of 3,000 objects of the same type after 1, 10,000, and 250,000 steps; grid  $200 \times 150$ . The size of the environment is 3-4 times larger than  $r = 50$ ; two stable teams emerge, working at a significant distance from each other. Nonconformists tend to rejoin one of those teams shortly. **(b)**: Sorting of 900 objects of 3 types (300 objects of each type) after 1, 10,000 and 50,000 steps; grid  $80 \times 60$ . The relative magnitudes of the grid size and  $r$  allow the entire agent population work as a single team most of the time. First, a cluster of one type of objects is consistently formed. Then nonconformists start to appear, switching the entire group to new tasks. (Note that pucks being carried by agents are not displayed here.)

ceases its nonconformist status and starts acting like any other conformist agent. Note that  $A$  will not gain nonconformity again from its colleagues which may still be nonconformists (because of using slightly outdated estimations of  $|h_A|$ ). Therefore, the entire group will eventually lose its nonconformist status and will become subject to honest conformist competition with other groups. If  $N_G > \frac{N}{2}$ , then, whenever a nonconformist is spawned, it will tend to create a new majority, switching the entire agent population to a new task.

As an illustration, Fig. 1 shows how the simulation of the sorting process looks like roughly one hundred iterations after a nonconformist appeared. A few important things can be noted. First, just before a nonconformist emerged, the entire population had been collecting red pucks to the cluster situated at the bottom. Since there are very few red pucks left to be collected (in this example, no isolated pucks are left, but often this is not the case), the agents have very low estimations of  $u$ , resulting in  $p_n$  large enough to create a nonconformist. Next, note that the nonconformist has already recruited many other agents which now have  $\psi > 0$ . According to Eq. 9, it is very likely that 4 agents that are still working on red pucks will shortly join the nonconformists. Interestingly enough, a couple of agents working in the “nonconformist” group have already stopped being nonconformists ( $\psi$  has become zero). This is because their  $|h_X|$  values have surpassed the  $N_G$  threshold (see Eq. 10). Agents that are farther away from the nonconformist home location have less chance to communicate with their colleagues; thus, their  $|h_X|$  increase more slowly, and they still consider themselves nonconformists. In 100-200 iterations, the entire population switches to green pucks, and all nonconformists become conformists again. Once almost all green pucks are collected, we can expect another nonconformist to appear.

The model described contains a number of parameters that can be tuned to achieve a desired balance between conformity and nonconformity. The next section offers experimental results showing how different values of some of those parameters affect the performance of the developed social model.

## Experiments

Our experiments are conducted in a Monte-Carlo simulation which is functionally as close as possible to the simulation used by Deneubourg et. al. (Deneubourg et al., 1991). We use a grid-based environment and do not allow cells to be occupied by more than one object and one agent at the same time. Each iteration of the simulation, the agents are updated in random order. During the update cycle, each agent communicates with one random member within its communication range  $r$  and then performs an action depending on its current state and perception (e.g., moves one cell toward its home location, or picks up an object). After the com-

munication session is completed, the agent is not allowed to communicate for the next  $T_S = 5$  time steps (it continues, however, its sorting work). This is done to reduce computational costs of the simulation. In addition, whenever a conformist becomes a nonconformist, it is not allowed to communicate until it settles down at its newly generated position. This is because the new nonconformist does not yet know its own task – it will be determined based on the type of the first object it encounters after its new home location is found. Finally, if an agent tries to become a nonconformist by generating a random number and comparing it with the probability  $p_n$  and fails, its next chance to do so is scheduled in  $T_N = \frac{T_U}{2}$  time steps. This is done to let  $n_u$  accumulate updates before firing  $p_n$  again. The general process of clustering and sorting can be seen in Fig. 2.

To assess the performance of the developed model, we collect two types of statistics: the size of the largest cluster and the number of clusters. We define clusters as follows: 1) An isolated object is a cluster of size 1; 2) An object  $q$  belongs to a cluster  $Q$  if  $q$  is of the same type as objects in  $Q$  and is located in an adjacent cell to any of the objects in  $Q$ .

Each experiment uses the following defaults:  $N_U = 10$ ,  $T_U = 500$ ,  $N_G = \frac{N}{4}$ ,  $N = 50$ ,  $r = 40$ ,  $l_h = l_x = 1$ ,  $l_c = 0.1$ ,  $c = 5$ , grid:  $80 \times 60$ , 3 types of objects, 300 objects of each type. If for any of these parameters another value is used, it is explicitly stated so in the caption of the relevant figure. For each experiment, we ran 30 trials and averaged the results. All plots show mean values accompanied by error bars of  $\pm 1.96$  standard errors of the mean; thus, the error bars correspond to 95% confidence intervals of the mean. For each set of experiments, Shapiro-Wilk tests have been conducted which consistently produced  $p$ -values that are greater than 0.05; thus, there is no reason to reject the hypothesis that our experimental data are not normally distributed.

As it is clear from Fig. 3, the group of socially intelligent agents demonstrates better performance than ALR agents. We included homing agents without a social model into benchmarks in Fig. 3 as well, in order to understand what part of the performance boost acquired by social agents is actually due to their social abilities as opposed to the performance boost gained due to the homing mechanism.

To estimate the influence of different parameters on the overall performance of the model, we conducted a series of experiments where we varied  $l_x$ ,  $c$ ,  $l_h$ ,  $l_c$ , and  $r$ .

As one might expect, smaller values of  $l_x$  result in a relatively quick convergence of the population to one task; thus, the number of clusters decreases relatively slow (because objects of the other two types are consistently ignored), but the size of the largest cluster grows faster (Fig. 4). Note that at  $t \approx 12,000$  the first nonconformists appear; conformists are recruited by nonconformists (see Eq. 9) and start form-

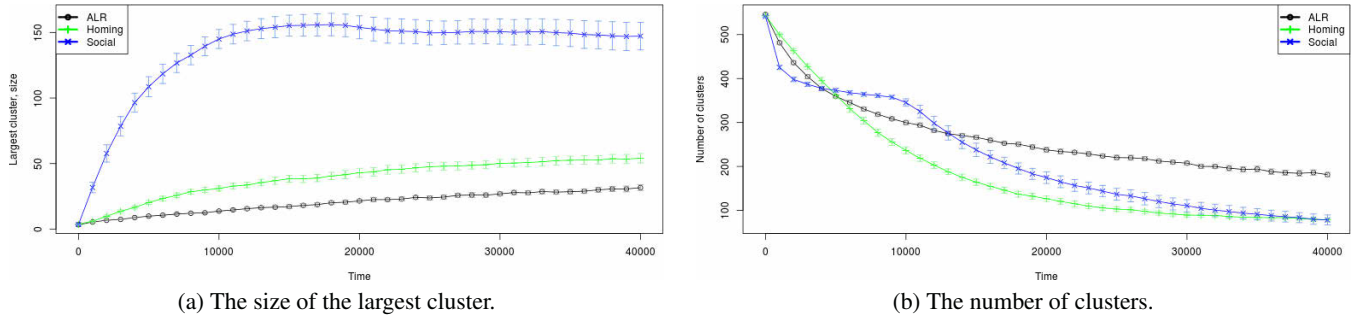

Figure 3: Experimental results for three modes: ALR agents, homing agents (no social model), and social agents; grid:  $120 \times 100$ .

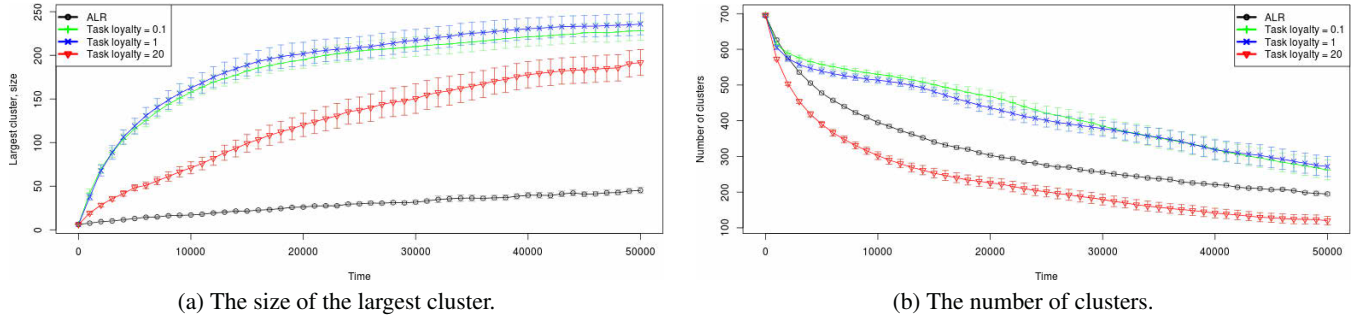

Figure 4: The influence of task loyalty  $l_x$  on the performance. Four modes: ALR agents, social agents with  $l_x = 0.1$ ,  $l_x = 1$ , and  $l_x = 20$ .

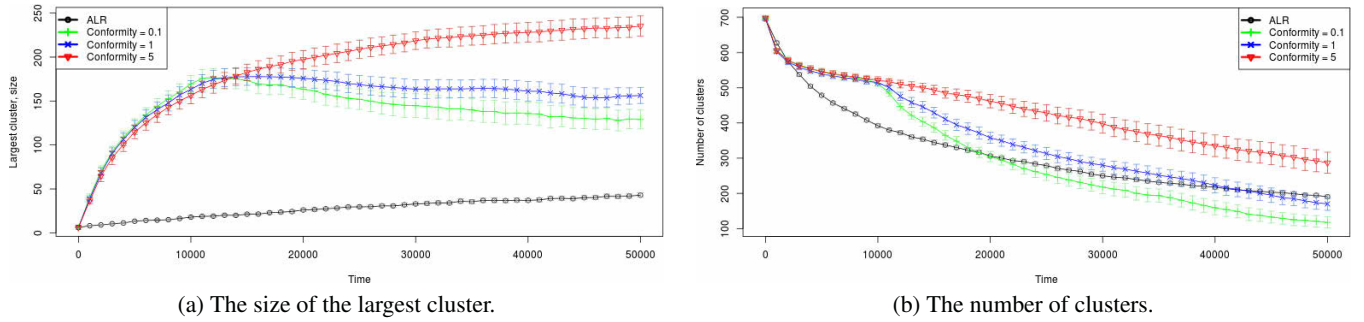

Figure 5: The influence of conformity  $c$  on the performance. Four modes: ALR agents, social agents with  $c = 0.1$ ,  $c = 1.0$ , and  $c = 5.0$ .

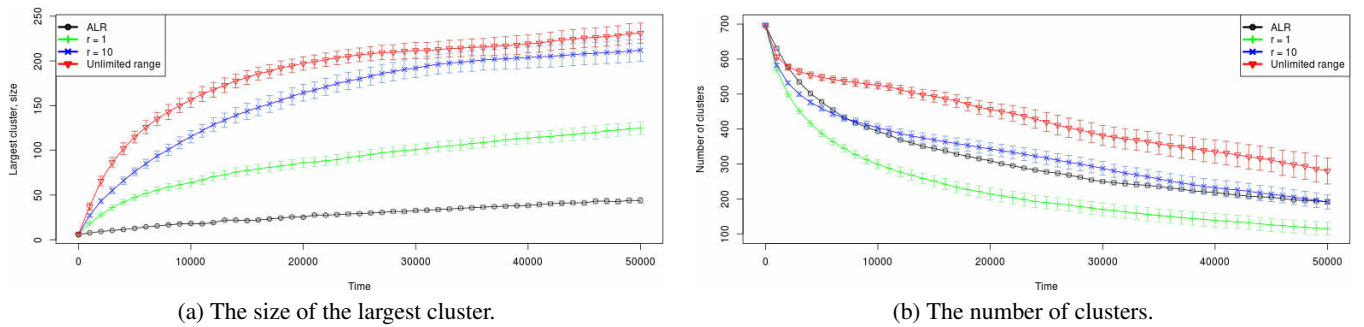

Figure 6: The influence of communication range  $r$  on the performance. Four modes: ALR agents, social agents with  $r = 1$ ,  $r = 10$ , and  $r = \infty$ . The grid size, similarly to previous experiments, is  $80 \times 60$ .

ing larger groups, and, as a result, the number of clusters starts decreasing faster.

Conformity  $c$  prevents agents from defecting from the course of majority. Fig. 5 shows that with large values of conformity the entire population works steadily on one task as few or no nonconformists emerge. Thus, the size of the largest cluster increases, but the overall number of clusters declines relatively slowly. On the contrary, smaller values result in a situation when many nonconformists with different home locations appear, effectively dismantling the agent population. In this case, the largest cluster is gradually destroyed by competing nonconformists.

The influence of the  $l_c$  and  $l_h$  parameters is less significant; relevant figures are omitted due to lack of space.

In our final series of experiments, we estimated the influence of the communication range  $r$  (Fig. 6). Agents with limited  $r$  have less chance to encounter each other; therefore, establishing cooperation is rather unlikely. It is quite natural that such agents show performance similar to non-social homing agents.

Similarly to the trade-off between exploitation and exploration in genetic algorithms, there is a trade-off between conformity and nonconformity in the proposed social model. Conformity is vital for cooperation, avoiding conflicting goals, and convergence; nonconformity, on the other hand, is useful for exploring the task space in search for new goals. Small values of task loyalty  $l_x$  combined with large values of conformity  $c$  may be used to generate agents that tend to work collaboratively and consistently on creating one large cluster, ignoring other tasks. If it is more important to quickly decrease the number of clusters, large values of  $l_x$  and home loyalty  $l_h$  may be used. Note that the described social model can be reduced to the homing algorithm described on page 2 by assuming  $l_x = \infty$ ,  $l_h = \infty$ , and  $c = \infty$ .

## Conclusions

In this paper, we have proposed a model of conformity and nonconformity, a social phenomenon observed in human society. We tackled a well-known problem, collective distributed sorting. Our approach originated in the domain of swarm intelligence, but evolved into *socially intelligent* approach as the social awareness of agents increased. We provided evidence that using the ideas of conformity and nonconformity can be beneficial in artificial multi-agent systems and can increase performance of a task.

The algorithm described in this paper is extreme in the sense that our agents act like *zero-intelligent* particles (Bentley and Ormerod, 2011); that is, the decision to change the home location and/or the task being carried out is based purely on the number of other agents working at that home location and/or on that task. Our experimental results indicate that even this extreme model, based only on social information, is useful and can be applied in collective robotics. Further research could be conducted to reveal

whether adding the social component of intelligence to the agents that are already capable of making informed decisions can increase the effectiveness of the robot group as a whole.

## Abstract

Physiological studies suggest that the integration of neural circuits and biomechanics (e.g., muscles) is a key for animals to achieve robust and efficient locomotion over challenging surfaces. Inspired by these studies, we present a neuromechanical controller of a hexapod robot for walking on soft elastic and loose surfaces. It consists of a modular neural network (MNN) and virtual agonist-antagonist mechanisms (VAAM, i.e., a muscle model). The MNN coordinates 18 joints and generates basic locomotion while variable joint compliance for walking on different surfaces is achieved by the VAAM. The changeable compliance of each joint does not depend on physical compliant mechanisms or joint torque sensing. Instead, the compliance is altered by two internal parameters of the VAAM. The performance of the controller is tested on a physical hexapod robot for walking on soft elastic (e.g., sponge) and loose (e.g., gravel and snow) surfaces. The experimental results show that the controller enables the hexapod robot to achieve variably compliant leg behaviors, thereby leading to more energy-efficient locomotion on different surfaces. In addition, a finding of the experiments complies with the finding of physiological experiments on cockroach locomotion on soft elastic surfaces.

## Introduction

There are increasing demands for robots to walk on a series of diverse terrains (Ozcan et al., 2010; Qian et al., 2012). However, few robots can walk on soft elastic (e.g., sponge) and loose (e.g., gravel and snow) surfaces. This is because traversing these surfaces efficiently requires variable compliance of legs (Spence, 2011; Bermudez et al., 2012). Traditionally, the variable compliance of legged robots can be achieved by passive compliance mechanisms (Ham et al., 2009) and/or active compliance control (Görner and Hirzinger, 2010). For example, by using active compliance control with joint torque feedback, a hydraulically actuated quadruped robot (i.e., HyQ, 90 kg) has been developed for moving over terrains (Boaventura et al., 2012). Nevertheless, the complex mechanical and sensing components of the HyQ robot greatly increase its size and mass, thereby not fitting for developing small legged robots. Yet a small six-legged robot (i.e., EduBot, 3 kg) has been designed by using physically passive variable compliant legs

(Galloway et al., 2011). The experimental results show that stiffer legs allow its faster locomotion on soft surfaces.

In contrast to the robot experimental results, owing to energy efficiency, biological study has shown that cockroaches (i.e., *Blaberus discoidalis*) use their softer legs on soft surfaces (Spence et al., 2010; Spence, 2011). This finding reveals a neuromechanical control strategy of hexapod locomotion on soft surfaces. In fact, the strategy is not the result of a single component rather interactions between a nervous system, a musculoskeletal system and the environment. Inspired by this, the work here proposes a novel neuromechanical controller of a hexapod robot for walking on soft elastic and loose surfaces. The neuromechanical controller consists of a modular neural network (MNN) coordinating leg movement and virtual agonist-antagonist mechanisms (VAAM) changing the compliance of legs. The changeable compliance is simply achieved by altering two internal parameters of the VAAM without physical passive compliant mechanisms (Ham et al., 2009) or joint torque sensing (Görner and Hirzinger, 2010). Employing this controller allows the robot to walk on different surfaces with energy efficiency. Besides, a finding of robot walking complies with the finding of physiological experiments on cockroach locomotion on soft elastic surfaces (Spence et al., 2010; Spence, 2011).

## Neuromechanical Controller of a Hexapod Robot

The experimental robot is a hexapod robot (5.4 kg) (see Fig. 1 (a)). Each three-jointed leg has a TC (Thoraco Coxal) joint allowing the motions of forward and backward, a CTr (Coxa Trochanteral) joint allowing the motions of elevation and depression, and a FTi (Femur Tibia) joint allowing the motions of extension and flexion (see Fig. 1 (b)). Each joint is physically driven by a standard servo motor. There is a force sensor used for detecting the analog signal at each leg (see  $f_{c1-6}$  in Fig. 1 (a)). A current sensor installed inside the body of the hexapod robot is used to detect electrical current used for all motors and sensors of the hexapod robot. For more details of the hexapod robot, we refer to (Manoonpong et al., 2013).

Figure 1: A hexapod robot (a) Six legs and six foot sensors  $fc_{(1-6)}$ . (b) A three-jointed leg.

## Modular Neural Network (MNN)

The modular neural network (MNN) is a biologically-inspired hierarchical neural controller (McCrea and Rybak, 2008), which generates signals for leg and joint coordination of the hexapod robot. The MNN consists of a central pattern generator (CPG, see Fig. 2 (a)), a phase switch module (PSM, see Fig. 2 (b)) and two velocity regulating modules (VRMs, see Fig. 2 (c)). All neurons of the MNN are modelled as discrete-time non-spiking neurons. The activity  $H_i$  of each neuron develops according to:

$$H_i(t) = \sum_{j=1}^m W_{ij} o_j(t-1) + B_i, i = 1, \dots, m, \quad (1)$$

where  $m$  denotes the number of units,  $B_i$  is an internal bias term (i.e., stationary input) to neuron  $i$ ,  $W_{ij}$  is the synaptic strength of the connection from neuron  $j$  to neuron  $i$ . The output  $o_i$  of all neurons of the MNN is calculated using a hyperbolic tangent ( $\tanh$ ) transfer function, i.e.,  $o_i = \tanh(H_i), \in [-1, 1]$ . The CPG consists of only two neurons with full connectivity (see Fig. 2(a)), where  $B_1 = B_2 = 0.01$ . The weights  $W_{12}$  and  $W_{21}$  are given by:

$$W_{12}(S) = 0.18 + S, W_{21}(S) = -0.18 - S, \quad (2)$$

where  $S \in \mathbb{R}_{[0,0.18]}$  is the input of the modular neural network, which determines walking patterns of the hexapod robot. The speed of its leg motion increases with increasing  $S$ . Here, we set  $S = 0.04$  resulting in slow walking behavior, which leads to stable and energy-efficient locomotion on non-flat surfaces (Manoonpong et al., 2013).

The PSM is a generic feed-forward network consisting of three hierarchical layers with ten hidden neurons (i.e.,  $H_3 - H_{12}$ ). The outputs of the PSM are projected to the FTi (i.e.,  $F(R, L)_{(1,2,3)}$ ) and CTr (i.e.,  $C(R, L)_{(1,2,3)}$ ) motor neurons (see Fig. 2 (d)), as well as the neurons  $H_{13}$  and  $H_{14}$  of the two velocity regulating modules (VRMs, see Fig. 2 (c)). The two VRMs are feed-forward networks projecting their outputs to the TC motor neurons  $T(R, L)_{(1,2,3)}$  (see Fig. 2 (d)). In the neuromechanical controller, the outputs  $N_{1-18}$  of the motor neurons are the neural activations of 18

Figure 2: Modular neural network. Output neurons (i.e.,  $N_{(1-18)}$ ) represent the neural activations of 18 joints of the hexapod robot. All connection strengths together with bias terms are indicated by the small numbers except some parameters of the VRMs ( $a = 1.7246, b = -2.48285, c = -1.7246$ ). Delays  $\lambda_L$  and  $\lambda$  between motor neurons (i.e.,  $N_{1-18}$ ) are set to:  $\lambda_L = 48$  time steps,  $\lambda = 16$  time steps. Abbreviation are:  $TR(L)_{1,2,3}$  = TC joints of the Right(Left) Front, Middle, Hind legs,  $CR(L)_{1,2,3}$  = CTr joints of the Right(Left) Front, Middle, Hind legs,  $FR(L)_{1,2,3}$  = FTi joints of the Right(Left) Front, Middle, Hind legs.

joints of the hexapod robot.  $N_{1-18}$  enable its legs to perform fast swing and slow stance phases (see Fig. 3). Delays  $\lambda_L$  and  $\lambda$  between the outputs of motor neurons are fixed (see Fig. 2 (d)). For more details of the MNN, we refer to our previous work (Manoonpong et al., 2013). However, the previous work did not consist of muscle-like mechanisms (e.g., virtual agonist-antagonist mechanism (VAAM)). Including the VAAM allows the hexapod robot to achieve more energy-efficient locomotion (described below).

## Virtual Agonist-antagonist Mechanism (VAAM)

The virtual agonist-antagonist mechanism (VAAM) consists of a pair of agonist and antagonist mechanisms (see Fig. 4(a)). They produce active and passive forces by its contractile and parallel elements (CEs and PEs, see Fig. 4(b)). In Fig. 4(a), the physical joint is driven by a pair of the virtual agonist-antagonist mechanism (VAAM, i.e.,  $M1$  and  $M2$ ). 'Virtual' means that the physical joint, physically driven by a standard servo motor, imitates muscle-like behaviors as if it were driven by a pair of agonist and antagonist muscles. The joint actuation relies on the CEs while the PEs govern joint compliance.

The parallel elements (i.e., PEs) are modelled as spring-

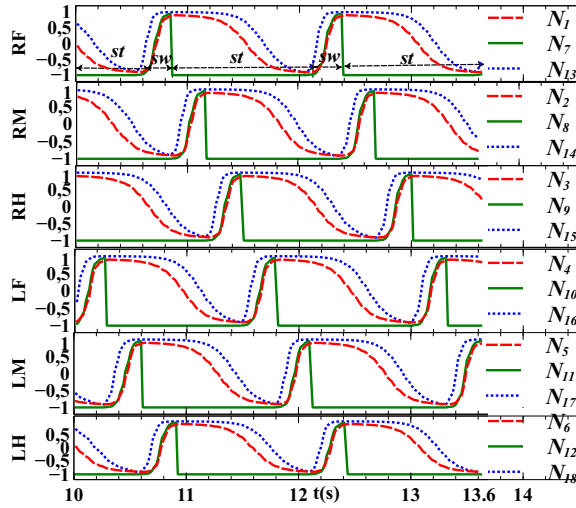

Figure 3: Outputs of motor neurons  $N_{1-18}$  between 10 s and 13.6 s. Abbreviations are: R(F,M,H) = Right (front, middle, hind) legs, L(F,M,H) = Left (front, middle, hind) legs. *st* = stance phase, *sw* = swing phase.

damper systems (see Fig. 4(b)). The matrix  $[f_1^P, f_2^P]^T$  of passive forces created by  $PE_{(1,2)}$  is the sum of two Hadamard products:

$$[f_1^P, f_2^P]^T = \Gamma_{2 \times 1} \circ L_{2 \times 1} + \Phi_{2 \times 1} \circ V_{2 \times 1}, \quad (3)$$

where

- $\Gamma_{2 \times 1}$  is the matrix of stiffness coefficients of  $PE_{(1,2)}$ , i.e.,  $\Gamma_{2 \times 1} = [K, K]^T$ ;
- $L_{2 \times 1}$  is the matrix of displacements of  $PE_{(1,2)}$ , i.e.,  $L_{2 \times 1} = [l_1^P - l_0, l_2^P - l_0]^T$ .  $l_0$  is the initial length of  $PE_{(1,2)}$ , which is set to:  $l_0 = 0.085$ ;
- $\Phi_{2 \times 1}$  is the matrix of damper coefficients of  $PE_{(1,2)}$ , i.e.,  $\Phi_{2 \times 1} = [D, D]^T$ ;
- $V_{2 \times 1}$  is the matrix of velocities of  $PE_{(1,2)}$ , i.e.,  $V_{2 \times 1} = [v_1^P, v_2^P]^T$ .

The active forces produced by the CEs are approximated by the product of the neural activation  $N_j$  and the activation intensities  $i_{(1,2)}$ . The matrix  $[f_1^C, f_2^C]^T$  of active forces generated by  $CE_{(1,2)}$  are represented by (see Fig. 4 (b)) :

$$[f_1^C, f_2^C]^T = N_j \times [i_1, i_2]^T, \quad (4)$$

where

- $N_j$  is the neural activation of  $CE_{(1,2)}$  (i.e.,  $N_j \in [-1, 1]$ ). It is one of the outputs  $N_{1-18}$  of the MNN (see Fig. 2 (d));
- $[i_1, i_2]^T$  is the matrix of activation intensities for  $CE_{(1,2)}$  (i.e.,  $i_{(1,2)} \in [-1, 1]$ ).

The total forces  $f_1^T$  and  $f_2^T$  are the sum of the active and passive forces produced by  $M1$  and  $M2$ . They are given by (derived from Eqs.(3) and (4)):

$$f_1^T = f_1^P + f_1^C = \underbrace{K(l_1^P - l_0) + Dv_1^P}_{f_1^P} + \underbrace{N_j i_1}_{f_1^C}, \quad (5)$$

$$f_2^T = f_2^P + f_2^C = \underbrace{K(l_2^P - l_0) + Dv_2^P}_{f_2^P} + \underbrace{N_j i_2}_{f_2^C}. \quad (6)$$

Figure 4: Virtual agonist-antagonist mechanism (VAAM) for joint control interacting with the ground surface. (a) A physical joint is driven by a pair of the VAAM with the lengths  $L_1$  and  $L_2$  (i.e.,  $M1$  and  $M2$ ). The interaction results in the force  $f^{ext}$ , which drives the joint  $P$  with the radius  $r$  via the shank with the length  $L$ .  $f^{ext}$  is sensed by a force sensor (i.e.,  $O$ ), and  $f^\perp$  is the amount of  $f^{ext}$  directed perpendicularly to the position of the joint  $P$ . (b) The VAAM consists of contractile (i.e.,  $CE_{(1,2)}$ ) and parallel (i.e.,  $PE_{(1,2)}$ ) elements for producing active and passive forces.

The antagonist mechanism  $M2$  (see Fig. 4 (a)) resists the extension of the joint angle  $\theta$  when receiving the force  $f^{ext}$ , which is sensed by a force sensor. Simultaneously, the agonist mechanism  $M1$  (see Fig. 4 (a)) produces opposing force against  $M2$ . Therefore, the directions of  $f_1^T$  and  $f^{ext}$  are counter-clockwise when the direction of  $f_2^T$  is clockwise.

Their torques acting on the joint  $P$  (see Fig. 4 (a)) are represented by:

$$\tau(f_1^T) = f_1^T r = (K(l_1^P - l_0) + Dv_1^P + N_j i_1) r, \quad (7)$$

$$\tau(f_2^T) = -f_2^T r = -(K(l_2^P - l_0) + Dv_2^P + N_j i_2) r, \quad (8)$$

$$\tau(f^{ext}) = f^\perp L = f^{ext} \sin(\theta) L, \quad (9)$$

where  $r$  is the radius of the joint  $P$ .  $f^\perp$  is the amount of  $f^{ext}$  directed perpendicularly to the position of the joint  $P$ .  $L$  is the length of the shank of the joint  $P$ . Note that the direction of torque  $\tau(f_2^T)$  is opposite to those of  $\tau(f_1^T)$  and  $\tau(f^{ext})$ . We consider the torque pointing outward from the page as the positive torque (e.g.,  $\tau(f_1^T)$  and  $\tau(f^{ext})$ ).

We apply Euler's laws of motion to the rotation of the joint  $P$  (see Fig. 4(a)). The net torque  $\sum \tau$  acting on the joint  $P$  is equal to the product of its moment of inertia  $I$  and angular acceleration  $\ddot{\theta}$ . It is given by:

$$I\ddot{\theta} = \sum \tau = \tau(f^{ext}) + \tau(f_1^T) + \tau(f_2^T). \quad (10)$$

Derived by Eq.(10) (see details in Appendix A), the motion equation of the joint  $P$  is given by:

$$I\ddot{\theta} = \underbrace{f^{ext} \sin(\theta) L}_{\text{torque by } f^{ext}} + \underbrace{r N_j}_{\text{torque by } f_{(1,2)}^C} - \underbrace{r(2K\theta r + 2D\dot{\theta} r)}_{\text{torque by } f_{(1,2)}^P}. \quad (11)$$

Equation (11) governs  $\theta$  of the joint  $P$  driven by the VAAM that is activated by the output  $N_j$  ( $j \in \mathbb{Z}_{[1,18]}$ ) of the MNN.

### Neuromechanical Control Strategies for a Hexapod Robot

The outputs  $O_{1-18} \in \mathbb{R}_{[-1,1]}$  (see Fig.5) of the neuromechanical controller are linearly scaled and transmitted to control the position of the standard servo motors driving the 18 joints of the hexapod robot. Different control strategies are applied in swing and stance phases.

#### Swing phase

When a leg is in swing phase (i.e.,  $f_i^{ext} = 0$ ,  $i \in \mathbb{Z}_{[1,6]}$ , see Fig. 5 (a)), the outputs  $O_{(i,i+6,i+12)}$  of its TC, CTr and FTi joints receive motor neuron signals  $N_{(i,i+6,i+12)}$  of the MNN as their inputs. They satisfy:

$$[O_i, O_{i+6}, O_{i+12}]^T = [0.4N_i, 0.15N_{i+6}, -0.02N_{i+12}]^T - [0.05, 0.86, 0.43]^T, i \in \mathbb{Z}_{[1,6]}. \quad (12)$$

#### Stance phase

Since there is only detection for vertical foot force in the leg, the TC joint allowing only horizontal motions is not effected by a pair of the PEs of the VAAM. Moreover,

Figure 5: The outputs  $O_{1-18}$  of the neuromechanical controller. (a)  $O_{1-18}$  control the 18 joints of the hexapod robot.  $f_{1-6}^{ext}$  are six analog signals, which are detected by the force sensors at the legs. (b) Relationship between  $O_{1-18}$  and  $\theta_{1-18}$ . The angle ranges of the TC, CTr and FTi joints are as follows:  $[\beta_1, \beta_2] = [0.785, -0.785]rad$ ,  $[\beta_3, \beta_4] = [-1.745, 0.785]rad$ ,  $[\beta_5, \beta_6] = [0.96, -1.222]rad$ .

we test two control setups (see Fig.6) for the FTi joint when the CTr joint is controlled by a pair of the PEs and CEs of the VAAM. The control setups are tested in a physical simulator (i.e., Iprzrobots simulator (Der and Martius, 2012)). The results of the physical simulation show that the FTi joint, purely controlled by a pair of the PEs of the VAAM, allows the hexapod robot to achieve the coordinated movement and stable locomotion (see Figs.6 (a) and (b)). The video clip of the test can be seen at <http://www.youtube.com/watch?v=fMLf6nIOWpM>.

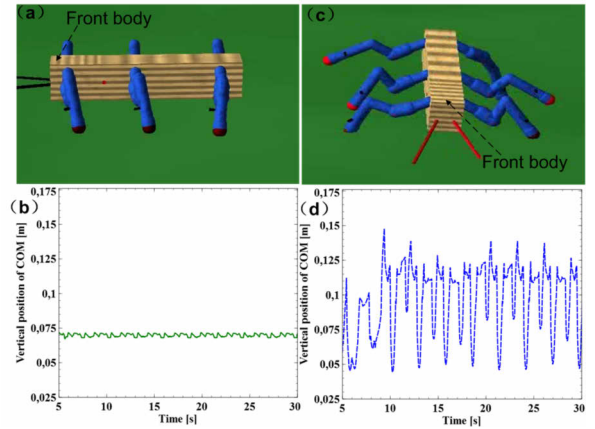

Figure 6: Two control setups for the FTi joint tested in a physical simulator. (a) Snapshot of stable walking of the hexapod robot at 15 s. (b) Vertical position of its body. (c) Snapshot of unstable walking of the hexapod robot at 15 s. (d) Vertical position of its body.

Therefore, the control strategy of its three-jointed legs during stance phase is as follows: each TC joint (i.e., proximal joint) is purely controlled by a pair of the CEs of the VAAM (i.e., pure actuation), each CTr joint (i.e., intermediate joint) is governed by a pair of the CEs and PEs of the

VAAM (the combination of actuation and compliance), and each FTi joint (i.e., distal joint) is driven by a pair of the PEs (i.e.,  $PE_1$  and  $PE_2$ ) of the VAAM (i.e., pure compliance) (see Fig. 7). The control strategy is also comparable to the findings revealed by three-jointed leg locomotion of the BigDog-inspired study (Lee et al., 2008; Raibert, 2008).

Figure 7: Control framework for a three-jointed leg of the hexapod robot in stance phase. (a) The three-jointed legs take the strategy of directional actuation and compliance (see text for details). (b) The control strategy for the leg. The function of compliance intensifies from the TC to FTi joints.

The relationship between the outputs  $O_{1-18}$  and the angles  $\theta_{1-18}$  of the joints is shown in Fig. 5(b). In concrete, the computations of  $O_{1-18}$  are as follows:

**FTi joints :** Each FTi joint is only driven by  $PE_{(1,2)}$  of the VAAM (see Fig. 7 (a)). Therefore, their neural activations  $N_{6 \times 1}$  are equal to zero,

$$N_{6 \times 1} = [0, 0, \dots, 0]^T, \quad (13)$$

where  $N_{6 \times 1} = [N_{13}, N_{14}, \dots, N_{18}]^T$ .

In addition, the forces  $f_{1-6}^{ext}$  directly result in the extension and flexion of the FTi joints. Therefore, the matrix  $\tau_{6 \times 1}^{FTi}$  of torques acting on the FTi joints is given by (derived from Eq.(9)):

$$\tau_{6 \times 1}^{FTi} = F_{6 \times 1}^\perp L_1, \quad (14)$$

where

$$\begin{aligned} F_{6 \times 1}^\perp &= F_{6 \times 1}^{ext} \circ \sin(\theta_{16 \times 1}) \\ &= [f_1^{ext} \sin(\theta_{13}), f_2^{ext} \sin(\theta_{14}), \dots, f_6^{ext} \sin(\theta_{18})]^T, \end{aligned}$$

Substituting Eqs.(13) and (14) into Eq.(11),  $\theta_{16 \times 1}$  is the sum of the Hadamard products:

$$\begin{aligned} I\ddot{\theta}_{16 \times 1} &= F_{6 \times 1}^{ext} \circ \sin(\theta_{16 \times 1}) L_1 \\ &\quad - r(2rK_{16 \times 1} \circ \theta_{16 \times 1} + \\ &\quad 2rD_{16 \times 1} \circ \dot{\theta}_{16 \times 1}), \end{aligned} \quad (15)$$

where

$$\begin{aligned} \ddot{\theta}_{16 \times 1} &= [\ddot{\theta}_{13}, \dots, \ddot{\theta}_{18}]^T, \dot{\theta}_{16 \times 1} = [\dot{\theta}_{13}, \dots, \dot{\theta}_{18}]^T, \\ K_{16 \times 1} &= [K_{13}, \dots, K_{18}]^T, D_{16 \times 1} = [D_{13}, \dots, D_{18}]^T, \end{aligned}$$

The angles  $\theta_{1m,1}$  ( $m \in \mathbb{Z}_{[1,6]}$ ) of the FTi joints can be linearly transformed into their outputs  $O_j$  (see Fig. 5).  $O_j$  are given by ( $j \in \mathbb{Z}_{[13,18]}$ ):

$$O_j = 0.92\theta_{j-12,1} + 0.12. \quad (16)$$

**CTr joints :** Each CTr joint is driven by  $PE_{(1,2)}$  and  $CE_{(1,2)}$  of the VAAM.  $CE_{(1,2)}$  are activated by one of the outputs  $N_{7-12}$  of the MNN (see Fig. 7 (a)). For example, the pair of the VAAM of the right front CTr joint (i.e., CR1) is activated by  $N_7$  of the MNN (see Fig. 2 (d)). The forces  $f_{1-6}^{ext}$  indirectly result in the elevation and depression of the CTr joint. The matrix of the CTr joint angles is  $\theta_{26 \times 1} = [\theta_7, \theta_8, \dots, \theta_{12}]^T$ . The computation of the torques generated by  $f_{1-6}^{ext}$  needs to be approximated, since there are no torque sensors at the CTr joint. Therefore, the matrix  $\tau_{6 \times 1}^{CTr}$  of the torques acting on the CTr joints is given by:

$$\begin{aligned} \tau_{6 \times 1}^{CTr} &= F_{6 \times 1}^{ext} \circ \vec{V}_{26 \times 1} \\ &= F_{6 \times 1}^{ext} \circ (L_2 \cos(\theta_{26 \times 1}) + \vec{V}_{16 \times 1}), \end{aligned} \quad (17)$$

where

$$\begin{aligned} L_2 \cos(\theta_{26 \times 1}) &= L_2 [\cos(\theta_7), \cos(\theta_8), \dots, \cos(\theta_{12})]^T, \\ \vec{V}_{16 \times 1} &= L_1 [\sin(\theta_{13}), \sin(\theta_{14}), \dots, \sin(\theta_{18})]^T, \end{aligned}$$

Substituting Eq.(17) to Eq.(11), the matrix  $\theta_{26 \times 1}$  of the CTr angles is the sum of the Hadamard products:

$$\begin{aligned} I\ddot{\theta}_{26 \times 1} &= F_{6 \times 1}^{ext} \circ (L_2 \cos(\theta_{26 \times 1}) + \vec{V}_{16 \times 1}) \\ &\quad + [rC_{6 \times 1} - 2r^2(K_{26 \times 1} \circ \theta_{26 \times 1} + \\ &\quad D_{26 \times 1} \circ \dot{\theta}_{26 \times 1})], \end{aligned} \quad (18)$$

where

$$\begin{aligned} \ddot{\theta}_{26 \times 1} &= [\ddot{\theta}_7, \dots, \ddot{\theta}_{12}]^T, \dot{\theta}_{26 \times 1} = [\dot{\theta}_7, \dots, \dot{\theta}_{12}]^T, \\ K_{26 \times 1} &= [K_7, \dots, K_{12}]^T, D_{26 \times 1} = [D_7, \dots, D_{12}]^T, \end{aligned}$$

The angles  $\theta_{2m,1}$  ( $m \in \mathbb{Z}_{[1,6]}$ ) of the CTr joints are linearly transformed into their outputs  $O_j$  (see Fig. 5).  $O_j$  are given by ( $j \in \mathbb{Z}_{[7,12]}$ ):

$$O_j = -0.8\theta_{j-6,1} - 0.38. \quad (19)$$

**TC joints :** All TC joints are purely controlled by  $CE_{(1,2)}$  of the VAAM.  $CE_{(1,2)}$  are activated by the outputs  $N_{1-6}$  of the MNN (see Fig. 7 (a)).  $N_{1-6}$  are linearly transformed into the outputs  $O_{1-6}$  of the TC joints. The matrix of the TC neuron outputs is  $T_{6 \times 1} = [N_1, N_2, \dots, N_6]^T$ .  $O_j$  are given by ( $j \in \mathbb{Z}_{[1,6]}$ ):

$$O_j = 0.4T_{j,1} - 0.05. \quad (20)$$

## Experimental Results

The proposed neuromechanical and pure neural controllers were implemented on the hexapod robot for walking on soft elastic (i.e., sponge) and loose (i.e., gravel and snow) surfaces. Changing the matrices of the stiffness coefficients of the FTi (i.e.,  $K1_{6 \times 1}$  in Eq.(15)) and CTr (i.e.,  $K2_{6 \times 1}$  in Eq.(18)) joints enables the legs of the hexapod robot to show variable compliance (see notations in Appendix B). Note that here, all damper coefficients of the CTr and FTi joints were set to:  $D(1,2)_{6 \times 1} = [0.1, 0.1, \dots, 0.1]^T$ . Due to the damper properties of the VAAMs, the noise of force sensor signals is filtered. Hence, we tested three setups for hexpod walking on the surfaces:

- Neuromechanical controller with high stiffness (HSC).  $K(1,2)_{6 \times 1}$  are set as:  $K1_{6 \times 1} = [4, 4, 6, 4, 4, 6]^T$  and  $K2_{6 \times 1} = [8, 8, \dots, 8]^T$ .
- Neuromechanical controller with low stiffness (LSC).  $K(1,2)_{6 \times 1}$  are set as:  $K1_{6 \times 1} = [3, 3, 5, 3, 3, 5]^T$  and  $K2_{6 \times 1} = [6, 6, \dots, 6]^T$ .
- Pure neural controller (PNC).

The pure neural controller (PNC) uses the outputs of the motor neurons of the MNN to directly drive the 18 joints of the robot. The computations of its outputs follow Eq.(12) for stance and swing phases. The free parameters of the proposed neuromechanical controller are chosen based on trial and error. The parameters of three setups allow the hexapod robot to achieve coordinated and stable locomotion, which have been tested in a physical simulator (i.e., Ipzrobots simulator (Der and Martius, 2012)). For each setup, the runs over each surface were repeated until ten successful runs<sup>1</sup> were obtained. For a successful run, the power consumption  $P_i$  and forward velocity  $v_i$  are given by:

$$P_i = 5A_i, v_i = \frac{\Delta DIS_i}{\Delta t}, i \in \mathbb{Z}_{[1,10]}, \quad (21)$$

where 5 Volts is the input voltage of the electrical board and motors of the hexpod robot.  $A_i$  is an average electrical current measured using a current sensor.  $\Delta DIS_i$  is the forward displacement during a time interval  $\Delta t$ . The performance of the runs was measured by "specific resistance"  $\varepsilon_i$  (Gregorio et al., 1997; Saranli et al., 2001).  $\varepsilon_i$  is determined by power consumption  $P_i$  and forward velocity  $v_i$ :

$$\varepsilon_i = \frac{P_i}{mgv_i} = \frac{P_i}{52.974v_i}, \varepsilon_{avg} = \frac{\sum_{i=1}^{10} \varepsilon_i}{10} \quad (22)$$

where  $mg$  is the weight of the hexapod robot, i.e.,  $mg = 52.974$  N. Lower  $\varepsilon_{avg}$  corresponds to more energy-efficient walking, which is desirable.

<sup>1</sup>The data of unsuccessful runs was discarded. In unsuccessful runs, the hexapod robot walked in unwanted directions.

Table 1: Average specific resistances  $\varepsilon_{avg}$  with standard deviations of the hexapod robot walking on sponge, gravel and snow surfaces

| Setup | Sponge               | Gravel               | Snow               |
|-------|----------------------|----------------------|--------------------|
| HSC   | 21.8 ( $\pm 0.9$ )   | 17.2 ( $\pm 0.7$ )   | 18.8 ( $\pm 0.5$ ) |
| LSC   | 19.7 ( $\pm 0.8$ )   | 29.3 ( $\pm 2.0$ )   | 22.3 ( $\pm 0.8$ ) |
| PNC   | 542.4 ( $\pm 63.8$ ) | 112.7 ( $\pm 13.0$ ) | -                  |

### Sponge surface

The interval  $\Delta t$  over one run was 27 s. A 1.5 m long sponge (i.e., three pieces of sponge glued together) was used as a soft elastic surface. The experiment result is shown in Table 1 and Fig. 8. The hexapod robot that was controlled by the neuromechanical controllers with the low (i.e., LSC) or high (i.e., HSC) stiffness consumed less energy than controlled by the pure neural controller (i.e., PNC). This is because LSC and HSC allow for variable joint compliance of the hexapod robot resulting in leg adaptations to sponge deformations (see Fig. 8 (a)). The experimental video can be seen at the link <http://www.youtube.com/watch?v=vEqylwMXfJE>.

Interestingly, LSC shows the lowest average specific resistance with 19.7. This experimental result shows that softer legs (i.e., LSC setup) allow the hexapod robot to achieve more energy-efficient locomotion, compared to stiffer legs (i.e., HSC setup). The finding complies with a finding of physiological experiments on cockroach locomotion. Owing to energy efficiency, cockroaches (i.e., *Blaberus discoidalis*) also use their softer legs on soft elastic surfaces (Spence et al., 2010; Spence, 2011).

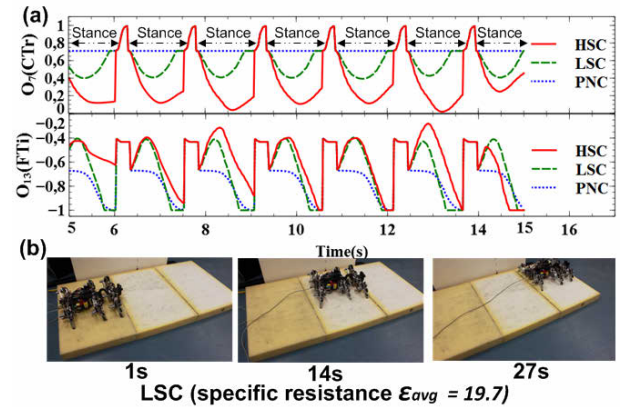

Figure 8: Comparisons of HSC, LSC, and PNC for walking on sponge surface. (a) Control signals  $O_7$  and  $O_{13}$  for the CTr and FTi joints of the right front leg. There are seven stance and six swing phases between 5 s and 15 s. (b) A series of photos shows hexapod robot walking controlled by LSC.

## Gravel and snow surfaces

The interval  $\Delta t$  over one run was 60 s. Gravel surface is a bed (i.e., the length is 2.4 m) of loosely packed gravels (i.e., gravel diameter  $\phi$  : 5 mm - 60 mm). The experimental result is shown in Table 1 and Fig. 9. HSC and LSC enable the hexapod robot to adapt its joint motions to different sizes of gravels (see Joint motion I and II in Fig.9 (a)), while PNC does not adapt the joint motions leading to difficulty of locomotion. In addition, the average specific resistance was lowest for HSC (i.e.,  $\varepsilon_{avg} = 17.2$ ), thereby leading to more energy-efficient locomotion. This is because HSC allows the legs of the hexapod robot to penetrate more deeply into gravel surface (see control signals  $O_7$  in Fig.9 (a)). The experimental video of walking on gravel surface can be seen at <http://www.youtube.com/watch?v=f2G4UzUQ6Iw>.

Figure 9: Comparisons of HSC, LSC and PNC for walking on gravel surface. (a) Control signals  $O_7$  and  $O_{13}$  for the CTr and FTi joints of the right front leg. There are six stance and five swing phases between 15 s and 25 s. (b) A series of photos shows hexapod robot walking controlled by HSC.

In addition to gravel surface, we also tested HSC, LSC and PNC for walking on another loose surface (i.e., snow), which has a thickness of 8cm. The experimental result also shows that HSC allows the hexapod robot to achieve more energy-efficient locomotion (see average specific resistance Table 1), compared to LSC. Note that we did not calculate average specific resistance of the hexapod robot controlled by PNC, since it got stuck in the snow. The experimental video of walking on snow surface can be seen at <https://www.youtube.com/watch?v=OkZiVNeQdCA>.

## Conclusion and Future Work

We implemented a neuromechanical controller on a hexapod robot for walking on sponge, gravel and snow surfaces. The controller coordinates 18 joints, generates basic locomotion, and allows for simply changing compliance of its legs for walking on the different surfaces. Due to the changeable

compliance, the robot can achieve more energy-efficient locomotion (i.e., lower specific resistance) on different surfaces. Softer legs (i.e., LSC setup) do better in locomotion on a soft elastic surface (i.e., sponge), while stiffer legs (i.e., HSC setup) are better for locomotion on loose surfaces (i.e., gravels and snow). In addition, on gravel surface, the specific resistance of the robot is 17.2 when it is controlled by the neuromechanical controller with HSC presented here. In contrast, its specific resistance increases to 56.63 when it is controlled by an adaptive neural locomotion controller presented in our previous work (Manoonpong et al., 2013), which does not have muscle-like mechanisms (i.e., virtual agonist-antagonist mechanism (VAAM)).

Central properties of the VAAM of our neuromechanical controller are: (1) it enables robot legs to simply change their compliance without the requirement of additional physically compliant mechanisms (Ham et al., 2009) or joint torque sensing (Görner and Hirzinger, 2010) and (2) it allows a hexapod robot to adapt its legs to deal with challenging surfaces (i.e., sponge, gravel and snow). In future work, we plan to compare the proposed neuromechanical controller with other adaptive leg controllers (e.g., forward model (Manoonpong et al., 2013)) in different surfaces (e.g., snow). And we will also implement an adaptive mechanism for automatically adjusting stiffness coefficients of the VAAM with respect to different walking speeds or gaits.

We also would like to thank Frank Hesse, Sakyasingha Dasgupta and Tomas Kulvicius for their fruitful discussions.

## Appendix A : Joint Motion Equation

Substituting Eqs.(7), (8) and (9) into Eq.(10), the motion equation of the joint  $P$  is given by:

$$I\ddot{\theta} = f^{ext} \sin(\theta)L + r[(K(l_1^P - l_0) + Dv_1^P + N_j i_1) - (K(l_2^P - l_0) + Dv_2^P + N_j i_2)]. \quad (23)$$

The lengths of  $PE_{(1,2)}$  (i.e.,  $l_{(1,2)}^P$ ) are equal to the lengths of  $M1$  (i.e.,  $L_1$ ) and  $M2$  (i.e.,  $L_2$ ),

$$l_1^P = L_1, L_2 = l_2^P. \quad (24)$$

In Fig. 4,  $M1$  is shortening when  $M2$  is lengthening. Therefore, the relationship between displacements of  $M1$  (i.e.,

$\Delta L_1$ ),  $M2$  (i.e.,  $\Delta L_2$ ) and  $PE_{(1,2)}$  (i.e.,  $\Delta l_{(1,2)}^P$ ) is given by:

$$-\Delta l_1^P = -\Delta L_1 = \Delta L_2 = \Delta l_2^P. \quad (25)$$

Here we postulate the relationship between displacements  $\Delta l_1^P$  of  $PE_1$ ,  $\Delta l_2^P$  of  $PE_2$  and the joint angle  $\theta$  as (derived by Eqs.(24) and (25)):

$$-(l_1^P - l_0) = -\Delta l_1^P = \theta r = \Delta l_2^P = l_2^P - l_0, \quad (26)$$

where  $r$  is the radius of the joint  $P$ . The relationship between velocities  $\dot{\Delta l}_1^P$  of  $PE_1$ ,  $\dot{\Delta l}_2^P$  of  $PE_2$  and the joint velocity  $\dot{\theta}$  is given by:

$$-v_1^P = -\dot{\Delta l}_1^P = \dot{\theta} r = \dot{\Delta l}_2^P = v_2^P. \quad (27)$$

Besides, since the motions of  $M1$  and  $M2$  are against each other, their activation intensities  $i_{(1,2)}$  are set to:

$$i_1 = -i_2 = 0.5. \quad (28)$$

## Appendix B : Notations

- $F_{6 \times 1}^{ext}$  is the matrix of the forces, i.e.,  $F_{6 \times 1}^{ext} = [f_1^{ext}, f_2^{ext}, \dots, f_6^{ext}]^T$ ;
- $F_{6 \times 1}^\perp$  is the Hadamard product of  $F_{6 \times 1}^{ext}$  and  $\sin(\theta 1_{6 \times 1})$ ;
- $L_1$  is the length of the link between the FTi joint and the end effector of the leg, e.g.,  $L_1 = 0.115$  m;
- $I$  is the inertia of the FTi and CTr joints, i.e.,  $I = 0.5 \times 10^{-3}$ ;
- $\ddot{\theta} 1_{6 \times 1}$  and  $\dot{\theta} 1_{6 \times 1}$  are the acceleration and velocity matrices of  $\theta 1_{6 \times 1}$ .  $r$  is set to 0.1;
- $K(1,2)_{6 \times 1}$  and  $D(1,2)_{6 \times 1}$  are matrices of the stiffness and damper coefficients of  $PE_{(1,2)}$ , which control the compliance of the FTi and CTr joints.
- $L_2$  is the length of links between the CTr and FTi joints, i.e.,  $L_2 = 0.075$  m;
- $\vec{V} 1_{6 \times 1}$  and  $\vec{V} 2_{6 \times 1}$  are matrices of the displacement vectors of the CTr and FTi joints relating to the forces  $f_{1-6}^{ext}$ .
- $\ddot{\theta} 2_{6 \times 1}$  and  $\dot{\theta} 2_{6 \times 1}$  are the acceleration and velocity matrices of  $\theta 2_{6 \times 1}$ .
- $C_{6 \times 1}$  is the matrix of the CTr neuron outputs of the MNN, i.e.,  $C_{6 \times 1} = [N_7, N_8, \dots, N_{12}]^T$ .

fabien.hervouet@lirmm.fr, eric.bourreau@lirmm.fr

## **Abstract**

This paper aims to introduce a flexible framework called *FIMO* dedicated to intrinsic motivation in developmental robotics. With this framework we want to offer a common way of implementing, testing and analyzing mechanisms related to intrinsically motivated algorithms. It may be seen as a generic complex open source framework for online exploration and structuring of learning spaces. We hereby lay both theoretical and practical foundations of our framework to encourage future experimental studies.

## **Introduction**

A commonly shared objective, in the developmental robotics community, as its name indicates, is insisting on the developmental part. It means that the most important aspect of any research led in this field lies in the path that leads to staged growth of learning. It may be about practical competences, conceptual comprehension or whatever a living organism with physical capabilities can practice. This implies that our goal is all about defining a model of developmental mechanisms, allowing a full open-ended incremental learning in an autonomous and interactive way, compliant and resilient with a real environment. The challenge is to propose a compromise between conciseness of the model and complexity it can generate as soon it is instantiated. But for an agent, developing competences is not that easy. It has to start with some coarse grained capabilities which are going to be refined throughout the developmental phase and life in general. This upgrowth is characterized by a double brain/body maturity, but also by the acquisition of sensorimotor experiences supporting learning. Inside the developmental robotics community, this is currently realized by inspecting multiple aspects of development. First the individual autonomous mental development which insists on finding mechanisms for an interactive system to develop itself solely using its very low-level sensory inputs and acting through its low-level motor outputs. The main second path for exploring development is the social learning. In this paper, we are interested in the first view.

Precisely, our working frame is mechanisms that can play the role of heuristics in order to focus and control the exploration of the potentially huge sensorimotor space of a situated and fully embodied agent. We believe that the goal of any developmental robotics algorithm is to design a control loop that – if executed on robot with physical capabilities – should reveal its own morphology affordance within its environment, through an unsupervised process. Moreover we also believe, as we already said, that the key challenge is to identify and implement low-level mechanisms that allow a long-term development as a scaffolding of capabilities. The more low-level these mechanisms are, the more the system can be considered as relevant. In the case of bio-inspired developmental robotics, we are interested in sensorimotor learning through the open-ended exploration of high-dimensional and complex bodies. This means we have to inspect and design scalable task-independent mechanisms that may involve the robot in a self autonomous skill practice. The main idea remains that the huge sensorimotor space can be divided into subspaces in order to facilitate the learning of the full space using intrinsic heuristics of space exploration. Another way to explain our view is to say that we are aiming at transferring the traditional cognitive modeling biases towards the natural limits and constraints imposed by the sensorimotor grounding embodiment.

In our case, we here underline the need for a framework for intrinsic motivation as we introduce it, with the capability to make parametric studies and introduce new bio-inspired ideas from state of the art neuroscience or developmental psychology research. We insist on the fact we propose in our framework *FIMO* facilitations for future improvements for some parts of the general intrinsically motivated algorithm it implements. In the rest of the article, we first propose a motivational background of the specific research field of ours. Then we present the practical foundations of this framework called *FIMO*. Then we zoom on the theoretical model of our view of intrinsic motivations. We conclude this paper by recalling the need for such a framework in our community, and draw some interesting application perspectives.

## Motivational Background

The question to ask when we get to implement some mechanisms like motivation in artificial agents, is about the origin of the notion of motivation. In this case, psychology has studied motivation a lot. The very first background of works about intrinsic motivation is the self-determination theory, which is the result of psychological research led by Deci and Ryan (1985) from the human point of view. This theory says that any individual has innate tendencies towards personal growth and vitality that are either satisfied in relation to their immediate environment. The theory also explains that there are three satisfactory needs that actors seek to satisfy: competence, relatedness and autonomy. Innate tendencies are enacted when these needs are fully satisfied. We will see that these founding psychological works have been at the base for transferring the notion of motivation *in silico*.

Historically, Schmidhuber (1991a) was the first to introduce research results about the importance of what he called *artificial curiosity*, in the sense of applying typical *human curiosity* to *artificial machines*. He argues that his research work has been driven by the simple idea that an optimal adapted and motivated agent is nothing but an agent trying to improve its compressed model of the world. He said that an agent with a prediction module, allowing the lossless compression of data by finding regularities in the world, is driven toward an optimal improvement. Schmidhuber (1991b) proposed to measure the learning progress of an agent by comparing difference of prediction for a same situation before and after the reality feedback. He therefore introduced the idea that an optimal curious agent's interest lies in the narrow corridor between what is simply too compressible and therefore uninteresting and boring, and what is not compressible at all because of a lack of regularity making it too complicated to learn.

Barto et al. (2004) have extended their own work in reinforcement learning (Sutton and Barto, 1998) with the notion of intrinsic motivation. They introduce an elaboration of the existing reinforcement learning framework that “encompasses the autonomous development of skill hierarchies through intrinsically motivated reinforcement learning”. Their model advocates the creation and use by an agent of structures of intrinsic generic rewards allowing adapted behavioral learning. They do not consider in any way external rewards.

Soon after the birth of the developmental robotics community (see Weng et al., 2001), Oudeyer and Kaplan (2004) introduced the *IAC* (*Intelligent Adaptive Curiosity*) algorithm. It explicitly refers to Schmidhuber's adaptive curiosity and must be linked with another paper published the same year by Steels (2004). The proposed mechanism is anchored at a sensorimotor level and allows low-level action selection in the high-dimensional sensorimotor space for a robot. This algorithm postulates that one way to provide

autonomy to a robot is to let it make its proper action choices, based on its experience, in order to maximize its learning. With this architecture an embodied agent is going to experiment grounded sensorimotor coordinations in order to learn the effects of its actions thanks to a unique action selection mechanism that tends to choose actions that improve prediction quality.

Baranes and Oudeyer (2010) then proposed an evolution to the original *IAC* algorithm called *SAGG-RIAC* which is of interest to us because of the competence acquisition paradigm it explores. The global principle remains the same except that this time, the agent has to choose sensory regions where it wants to return to, instead of choosing sensorimotor regions where it comes from. Practically, the *SAGG-RIAC* algorithm is based on alternating reaching phases (i.e. reaching a goal in what they call an operational space) and local exploration phases (i.e. improving the world comprehension toward the goal). The purpose of reaching phases is to test the reliability of the forward motor model while the purpose of exploration phases is to improve the inverse model of the system in the close vicinity of the current state. Exploration phases are triggered when the reliability of the local controller is too low. In the following section we explain some improvements to this algorithm we would like to introduce and experiment.

This research must also be linked with some other works by Blank et al. (2005) we fully agree with, where they argue that any intrinsic developmental algorithm has to be based on a recursive model that produces complex behavior and that it should rely on three concepts: abstraction, anticipation and intrinsic motivation.

## General Architecture of *FIMO*

*FIMO*<sup>1</sup> has the goal of bringing up a brand new open, flexible and extensible framework for research in the developmental robotics field working on agents driven by intrinsic motivations. We propose with this architecture, a solid and well-thought way of experimenting new ideas for the intrinsic motivation interested community. This section is dedicated to the presentation of *FIMO*, either the way it is architected, its pythonic foundations, its software architecture and workflow, and the default provided environments.

## Python Foundations

First of all, it is important to explain the Python foundations of this framework. We based our development on well documented, community supported and very powerful libraries such as *SciPy*, *NumPy*, *matplotlib* which are dedicated to scientific data processing. The first one Jones et al. (2001) is open-source software for mathematics, science, and engineering. It depends on the second one, which provides con-

<sup>1</sup>The Python open source code of the framework is available at <https://info-depot.lirmm.fr/republic/fimo> (public cloning repository) released under GNU GPLv3 license.

venient and fast  $N$ -dimensional array manipulation, with efficient numerical routines. The visualization module relies for its part on the third one Hunter (2007). Our point is that the techniques used in this framework have been already deeply tested and used by a lot of other researchers, and that they have proved their efficiency and their reliability.

### Software architecture

The global workflow of our framework *FIMO* is rather common and intuitive. Typically, the framework features an environment that describes in a formal way the being explored sensorimotor space, which is mandatory for bootstrapping the agent's living loop. Once the environment is chosen, we must also provide the agent with parameters and metrics – which may have a significant influence on its developmental trajectory – depending on the choices made at the instantiation time. Then, at the end of a run, i.e. when the program has tried to reach the certain amount of goals you asked it to perform, multiple data are dumped into log files. Typically, it includes the evolution of space partitioning into subregions, acquired sensorimotor raw data, interests of selected regions where objectives were generated and test results. Finally, another powerful advantage of the framework also lies in the visualization module made possible thanks to the logging process. This possibility to observe the result of any run instance makes it easier to understand and validate the configured parameters, metrics and other implemented ideas. We will illustrate the rest of the paper with some visualizations *FIMO* can offer.

### Environments

An environment as we defined and formalized it within our framework is all about the agent's acting possibilities. We mean that an environment should be seen as a complex interface between the sensory (or operational) space to explore, the motor space allowed for this exploration, and the combined result of these two. An environment must provide the sensory dimensions or operational dimensions, the motor dimensions, a starting state or rest position. It must also specify a function computing a new state given a current state and an action to execute, and a function that generates reachable coordinates in the sensory / operational space to be used for the examination. As a bias, you can predefine a region partitioning for the agent to start with, in order for instance to help it bootstrapping. The way we implemented the connection between environments and the main loop must allow to easily connect to some existing 3D simulated environments or to any physical robots following the same guidelines. Table 1 provides a summary of proposed simulated environments in *FIMO* and present their sensory and motor dimensions.

**Wheeled vehicle** The first provided environment is a very simple wheeled vehicle in an arena. The first version is only two dimensional (1D sensory space and 1D motor space).

| Environments                                     | a | b  |
|--------------------------------------------------|---|----|
| One-wheeled vehicle (OWV) 1D fully reachable     | 1 | 1  |
| OWV 1D not fully reachable                       | 1 | 1  |
| OWV 1D bump requiring sufficient inertia to pass | 1 | 1  |
| Two-wheeled vehicle (TWV) 2D squared area        | 2 | 2  |
| TWV 2D squared area with obstacles               | 2 | 2  |
| TWV 2D triangled area                            | 2 | 2  |
| Robotic arm (RA) with one joint                  | 2 | 1  |
| RA with two joints                               | 2 | 2  |
| RA with three joints                             | 2 | 3  |
| RA with fifteen joints                           | 2 | 15 |

Table 1: Summary of the variations of the main existing environments in *FIMO* presenting their distinctive feature(s), the size of their operational (a) and motor (b) spaces.

The second version is four dimensional (two sensory space, 2D motor space). Generally the shape of the arena is a square, but it could be different or contains obstacles. In the first version, the vehicle evolves in a 1D space and has a sole coordinate ( $x$ ), that is the distance to the front wall. In the second version, the vehicle evolves in a 2D space and has two coordinates ( $x; y$ ). It can move by performing an action ( $\Delta_x, \Delta_y$ ) representing a shift in the plane.

**Robotic Arm** We propose a second environment typically used – in particular in Baranes and Oudeyer (2010, 2013) – to test intrinsic motivation algorithms: a robotic arm (cf. figure 1<sup>2</sup>). The environment provided is a generic robotic arm that you can easily instantiate by defining the number of joints/limbs you want, and their respective length (or the unique length if ever).

Figure 1: Schematic successive positions of a 3 joints robotic arm environment at time  $t$  and  $t + 1$ .

<sup>2</sup>Here, each limb has the same length and  $\theta_i$  represent angles of each joint, relatively to  $\theta_{i-1}$ . The performed action that moves the end-effector from  $\sigma_t$  to  $\sigma_{t+1}$  coordinates in the operational space by trying to reach  $\gamma_{t+1}$  was  $\alpha = (\Delta\theta_1 = +115, \Delta\theta_2 = -140, \Delta\theta_3 = +40)$ .

The transition from end effector position to another one through a given action is computed using standard methods for forward position kinematics. An action is a vector of positive or negative  $\Delta$  for each joint  $(\Delta_{\theta_1}, \Delta_{\theta_2}, \Delta_{\theta_3})$ . It means the agent can only use relative moves from one  $(H_{x,t}, H_{y,t})$  to the next  $(H_{x,t+1}, H_{y,t+1})$  position.

### Theoretical Model

In this section we explain the theoretical model behind of *FIMO*. Thus, we present the main algorithm and every single parameters or metrics that the experimenter must use as such or improve, extend or change. Nevertheless, what we want to emphasize is that this algorithm needs to be configured by many parameters and metrics to be specified by the experimenter that can strongly influence the final behavior of the system and its evaluation.

The living loop algorithm as we call it, proposes a kind of reinforcement learning method, but it must be seen as an empty shell that must be completed with the right parameters to be able to observe the best behavior (see algorithm 1). Indeed, in the same way that one must specify an environment, the configuration parameters and the choice of metrics are essential and grouped in a *config.py* file. The interaction of the body/environment and the intrinsically motivated algorithm is something very delicate which requires the attention of the experimenter. One must see this guided exploration of sensorimotor space as a *complex system* as it is composed with multiple interconnected parts (different parameters and metrics to tune) which as a whole exhibit behavior not obviously predictable from the individual properties. The interaction of these parameters put together in the living loop algorithm may exhibit emergent properties. Moreover we believe that it may be possible to define some precise optimized setting for a specific environment.

In the rest of the section we present some of the general part of the framework (main algorithm, default regions structure and implemented learning method) as well as the criticals part that may be overridden with improvements (competence and interest measures, the way memory may be restructured). These parameters should be deeply studied in order to fit the need for a specific morphology, because we believe that the embodiment plays a major role in order to help determining fully appropriate, responsive, efficient and developmental settings.

Thus this is all about trying to find a compromise to encourage and facilitate effective and efficient exploration of space, without losing time in not interesting areas, while allowing rapid improvement for test result. Among the default implementation choices we present here, some have already been presented in Hervouet and Bourreau (2012).

### Living loop algorithm

Although we keep the overall operation of the original motivational living algorithm SAGG-RIAC Baranes and Oudeyer (2010), we extended the frame. The global

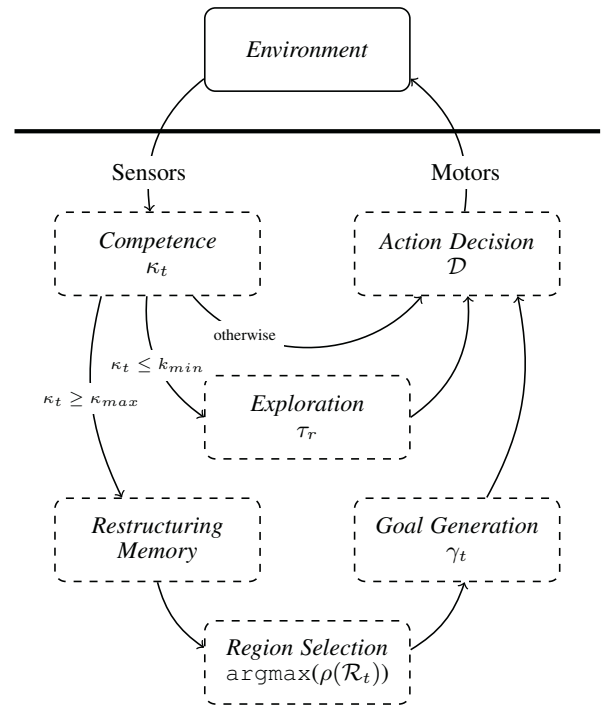

Figure 2: General algorithmic architecture of the intrinsically motivated living loop implemented in *FIMO*.

algorithmic architecture is presented in figure 2 and its implementation is presented in algorithm 1. With this implementation, we want to underline the flexibility of certain specific parts of the algorithm. We mean that the sequence of the algorithm is nothing but a generic system that aims at *exploring and structuring a sensory / operational space with partial data for sensorimotor learning*. Indeed we have to be aware of the strong influence of metrics and parameters that we may use to obtain more compliant or efficient behavior. This is the reason why we decided to emphasize the critical parts in the algorithm in order to be more illustrative. Each of them is studied in the rest of this section.

In a formal way, our architecture makes a distinction between *raw data*  $\xi_r$  accumulated during *exploration phases* (second loop in fig. 2) and more *structured data*  $\xi_g$  accumulated during *exploitation phases* (third loop in fig. 2). An exploration phase is triggered each time the agent is considered as incompetent and consist in accumulating  $\tau_r$  raw data about the consequences of actions the agent executes. In practice, exploration data represent a forward model of the body in the world. Exploitation phases consist in generating a goal and attempting to reach it in  $\tau_g$  times. Exploitation data represent the particular historical and motivational coupling between the agent and its environment, in the sense of Varela et al. (1991), i.e. the sensory configuration he has set itself for its goals that it tried to achieve by itself with varying degrees of success, according to the increase of its competence in relation to these goals.

As it is implicitly formalized, time is considered in the algorithm:  $\sigma_t$  always represents the agent's current state, which changes every time the agent performs an action  $\alpha_t$  using the *execute*( $\alpha$ ) method.

### Interest Measure (IM)

The measure of interest  $\rho$  qualifies the dynamic interest of a region. It is used to compute the most interesting region, the one with maximum  $\rho$  value (line 3), the agent is going to self-generate a goal in. The default one proposed in *FIMO* is based on the one introduced by Baranes and Oudeyer in Baranes and Oudeyer (2010) with one major difference. It is computed as follows:

$$\rho(\mathcal{R}_i) = \text{learningProg}(\mathcal{R}_i) + \text{diversification}(\mathcal{R}_i)$$

The learning progress is computed using experiments from exploitation phases ( $\xi_g$  for goal experiments) which are of the form:

$$\xi_{g,t} = (\sigma_t, \gamma_t, \mathcal{A}, \sigma_{t+i}, \kappa_t)$$

with  $\sigma_t$  the current sensory configuration state,  $\gamma_t$  the chosen goal to be reached,  $\mathcal{A}$  the motor configurations successively performed to achieve the goal with  $|\mathcal{A}| = i$ ,  $\sigma_{t+i}$  the new current state after execution of actions and the competence  $\kappa_t$  (explained in detail in a following section). The learning progress computation can be seen as a derivative of competences. Let  $\kappa_j$  be the competence of the  $j^{th}$  experiment stored in memory, and  $|\mathcal{R}_i|$  the number of experiments in a region.

$$\text{learningProg}(\mathcal{R}_i) = \frac{|\sum_{j=0}^{|\mathcal{R}_i|/2} \kappa_j - \sum_{j=|\mathcal{R}_i|/2}^{|\mathcal{R}_i|} \kappa_j|}{|\mathcal{R}_i|}$$

We chose to directly incorporate a UCT based Kocsis and Szepesvári (2006) diversification measure which takes into account in an incremental way the number of experiments conducted in the current region relative to the total number of experiments. It means that this mechanism will gently wake up regions whose direct learning progress is decreasing but for which it would be wise to generate a goal in just to make sure everything has been already either understood or misunderstood. Let  $n$  and  $n_i$  be respectively the total number of experiments and the number of experiments in the current region. Let  $c$  be a constant that allows to normalize the result of diversification measure.

$$\text{diversification}(\mathcal{R}_i) = c \times \sqrt{\frac{\ln n}{n_i}}$$

In summary, the interest measure  $\rho$  is composed by the addition of two dynamic but separate measures. The first one computes the learning progress in a given region, while and the second one tries to uniformly balance against the natural excessive regional intensification of the first one. This separation of the intensification measure and the diversification measure is of real interest for future improvements, because we will only have to deal with precisely defining the first one without taking into account the uniformisation process preventing overspecialization.

### Action Decision (AD)

The default decision method we propose is a simple algorithm that chooses the next action to perform in order to reach a goal driven through experience (line 7). We propose to compute action towards a goal using *k-nearest-neighbour* experiments chosen among previously acquired explorative experiments. These experiments ( $\xi_r$  for raw experiments) are of the form:

$$\xi_{r,t} = (\sigma_t, \alpha_t, \sigma_{t+1})$$

with  $\sigma_t$  the current sensory configuration state,  $\alpha$  the motor configuration determined at time  $t$  and finally  $\sigma_{t+1}$  the new current state after execution of action  $\alpha$ . These experiments must maximize two criteria: the initial and final states should be as close as possible respectively to current and goal states. The strategy then consists in generating a mean

action with respect to actions performed in these filtered experiments (with  $|K| = k$ ).

$$\mathcal{D}(\xi_r, \sigma_t, \gamma_t) = \frac{\sum_{u=1}^{|K|} \alpha_u}{k} \text{ where}$$

$$K = \{\xi_{r,u} \in \xi_r : \min(|\sigma_t - \sigma_u| + |\gamma_t - \sigma_{u+1}|)\}$$

### Competence Measure (CM)

Competence  $\kappa_t$  ranges in  $[\kappa_{min}; 0]$ , as it is computed in the original algorithm, with  $\kappa_{max}$  typically equal to  $-1$ . The default implemented measure sums distances for all sensors in  $S$  between the final sensory position minus the goal sensory position, relative to the start position minus the goal position. It means that we compute the shift between where the agent comes from, where it should have arrived and where it has finally arrived.

$$\kappa(\sigma_s, \gamma_t, \sigma_f) = \max\left(-\frac{|\sigma_f - \gamma_t|}{|\sigma_s - \gamma_t|}, \kappa_{min}\right)$$

with  $\sigma_s$ ,  $\gamma_t$  and  $\sigma_f$  respectively start, goal and final state  $\kappa_{min}$  the minimal competence (or maximal incompetence) and  $\kappa_{max}$  the very competent threshold. The 3D visualization of the competence value of the robotic arm evolving in a 2D space is presented in figure 3. We can observe the reachable area at the center.

Figure 3: 3D visualization of generated goals for an instance run of the robotic arm in the two dimensional operational space. The closer to 0 on the third axis the goals, the more competent the agent was to reach them. The greener the goals, the more recently they have been reached. Blue points represent goals for assessment.

### Restructuring Memory (RM)

A typical developmental and incremental process pushes the robot to start its learning from scratch. It can only make non-optimal decisions solely from previously acquired data. This implies that the robot acts very strangely at

the beginning because it does not hold enough information about the world it develops in. The figure 4 presents the result of a run instance with original operational space split into subregions of interest through time<sup>3</sup>. We can observe the naturally delimited reachable space because we add perfectly reached goals from where we arrive at the end of a reaching attempt. Moreover we can observe the reinforcement of generated goals in the vicinity of these natural embodiment limits. This shows that the agent seems to find interesting areas located near the limits it can reach, which must be considered as a good behavior.

Therefore, pushing the robot to split its sensorimotor space allows it to overcome the lack of information at the beginning of the developmental living process. This is this particular splitting condition that makes the strength of this approach because it allows *the isolation of coherent experiments*. This coherence may depend on the nature of the measure that determines the best split in a sensorimotor region. The default coherence measure implemented in *FIMO* is related to the notion of learning progress<sup>4</sup>, i.e. the derivative of learning.

Figure 4: Visualization of generated experienced goals and regions containing them in the split operational space for a robotic arm environment.

Thus the splitting condition needs to take into account knowledge and experience accumulated. Otherwise the agent will always tend to split again and again its space, which will probably be pointless. We wanted to propose a general way to be able to implement a kind of dual restructuring measure. Because it may be very interesting to

<sup>3</sup>The shape of the reachable area is not a full circle because of the limitation we added for each joint's absolute angle  $\theta_i$  to range between  $[0; 180]$ .

<sup>4</sup>But it could be related to any other idea that we could think of progress: better structuring memory, novelty, compression, etc. This is the reason why we should facilitate the implementation of new ideas by emphasizing replaceable metrics and parameters.

be able to elaborate a measure that would decide, depending on accumulated experience, not only how to split, but more how to reorganize the memory. This vision totally fits a developmental process. Thus we chose to combine these two mechanisms by proposing by default a dual measure for both splitting and merging. It tries to maximize the absolute value of the difference between the learning progress in the two subregions relative to the current learning progress in the mother region.

$$\mu(\mathcal{R}_1, \mathcal{R}_2, R) = \frac{|LP(\mathcal{R}_1) - LP(\mathcal{R}_2)|}{LP(R)}$$

It means that in the splitting case we will split the current region  $R$  if it contains two subregions  $\mathcal{R}_1$  and  $\mathcal{R}_2$  exhibiting better learning progress, relatively to the current learning progress in the region  $R$ . On the other hand in the merging case, we will merge two regions that have been split possibly a long time ago when the agent didn't hold enough information: the current region  $\mathcal{R}_1$  should be merged with another region  $\mathcal{R}_2$  into a sole region  $R$  if the learning progress of  $R$  exhibits a better evolution than  $\mathcal{R}_1$  and  $\mathcal{R}_2$ .

### Regions as a graph structure

In order to propose more genericity for future implementations we chose to upgrade the tree structure of regions used since *IAC* Oudeyer and Kaplan (2004). We decided to introduce a graph structure of regions (cf. figure 5) because we considered that the tree representation was a limitation. We believe that, by its more scalable and flexible nature, the graph structure facilitates from an operational point of view potential reorganization as we will discuss in the following section. In particular it may allow the creation of non-convex regions by merging already existing region whether they are physically adjacent or not.

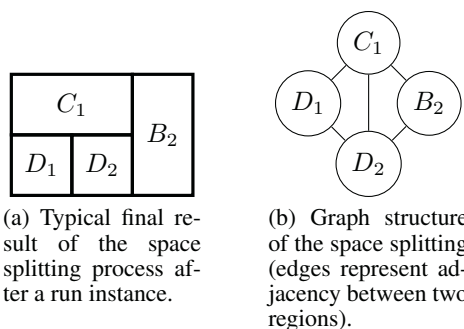

Figure 5: Illustration of the graph structure for regions. On the left it represents the result of a 2-dimensional sensory space splitting process, while on the right the way this is handled in memory.

### So, how to evaluate?

To propose a framework laying the foundations to encourage the community to easily implement and test new ideas is one thing, to propose a way to evaluate them is another. Indeed setting up such a framework obviously also involves setting

up an experimental validation process as a common foundation for evaluation, which is not a trivial thing. As pointed out by Meeden and Blank (2006) a few years ago, the evaluation question is fundamental, especially in the frame of autonomous developmental robotics.

We generally make a distinction between the formative and the summative assessments in the literature. A quotation attributed to Robert Stakes in Scriven (1991) tends to explain the difference between them: "When the cook tastes the soup, that's formative; when the guests taste the soup, that's summative".

*Formative assessment* represents the global operation of the intrinsically motivated process proposed living loop algorithm. Indeed, the main role of formative assessment lies in its subjective regulatory function of the learning process within the system, where the learner must be able to measure progress made and progress to be made.

*Summative assessment* must be seen as a more common and accepted way permitting to test learning acquisition from outside of the system, by certifying whether knowledge has been assimilated. This means we must provide in *FIMO* an external way, considered as objective as possible, to measure the relevance and importance of potential improvements as explained in Hervouet (2013). Practically in *FIMO* we implemented a measure that circumscribes the evaluation of the evolution of the competence through time. The idea is to select a set of arbitrary uniform reachable goals and compute a mean incompetence for reaching them.

Figure 6: Evolution of the mean incompetence for a given set of reachable goals for different environment and parameters (1 means bad competence while 0 means very competent).

As an illustration, we propose on figure 6, a comparison of assessment scores for a set of different settings under different environments. From bottom: (1) 1-joint robotic arm; (2,3,4) three instantiations with the same settings of a 2-

joints robotic arm; (5) 15-joints robotic arm; (6) 2-joints robotic arm but with random action (baseline).

## Conclusions & Perspectives

In this paper we argue that in the developmental robotics community, and more specifically in the subcommunity interested in intrinsically motivated robotics, there are multiple ways to propose some improvements. With the proposed framework *FIMO*, we clearly made an attempt, starting from an existing approach, to extend the frame. It is absolutely not the purpose of this article to introduce some fascinating new metrics or define more precisely some of the parameters. We are not saying we have found the best something or a better somewhat. In contrast, we believe that this will be the purpose with forthcoming publications, thanks to the implementation of our framework and the facilitations it brings up for the evaluation and comparison of future improvements. Notwithstanding, there are various parameters waiting to be tuned. However, the fact remains that, to illustrate this purpose, we proposed some default parameters, metrics or even other surroundings learning features, but they are presented as an indication because we were confronted to the need to set up the framework with implementation choices.

We consider *FIMO* as a necessary formal step toward an open future of intrinsic motivations work because it will help future contributions and improvements to emerge. Our willingness for genericity, must be seen as a contribution in itself, in the sense of the facilitation for novel contributions.

Beyond this evident aspect, we could draw an interesting future for our framework. Although defining metrics is typically human compatible (and especially computer incompatible), simple parameters should not be set manually. As a spreading field, evolutionary robotics provides some exciting opportunities for the developmental robotics community, and could help us in this context. We mean that the very practical way of implementing evolutionary mechanisms consists in growing individuals with different genomes, and to make reproduce the best adapted ones in order to grow the next generation. This process can be reiterated as long as you may observe some interesting progress towards adaptation to the environment. That is why we truly believe that a possible *EvoFIMO* could constitute a very interesting perspective for the development of our research as well as for the whole community.

# A practical approach to Humanoid Introspection

Ignazio Infantino<sup>1</sup>, Giovanni Pilato<sup>1</sup>, Riccardo Rizzo<sup>1</sup> and Filippo Vella<sup>1</sup>

<sup>1</sup> ICAR - CNR, Viale delle Scienze ed.11, Palermo, Italy

## Abstract

We describe an approach for a humanoid robot to understand its internal state (Infantino et al. (2013)). The method is based on self observation and communication with the external world, according to the idea of introspection given by Sloman (2010). The robot introspection arises from information about physical components and software modules. This information is translated in a spatial representation of the hardware and software components of the robot through a SOM, which links the state representation of the robot with an high level representation given by an ontology. The ontology is furthermore linked to a linguistic module that makes it possible the interaction with human beings through a conversational agent.

## Introduction

The interaction between man and robot can benefit from models of the human mind and its cognitive abilities. One aspect that has not received enough attention is the mechanism that allows the robot to have a kind of self-awareness (Birlo and Tapus, 2011). Self-awareness, including the body physical parts and management functions related to them, is often referred to an a priori knowledge and it is usually implicitly integrated into the architecture. We will illustrate a possible approach for the realization of an introspective capacity (at present mainly oriented to the physical components of the robot).

Based on an empirical approach, our idea of introspection of the robot, starts from the analysis of information obtained automatically by the embedded software and its related documentation, in particular regarding the relationship (direct or explicit) between the physical components and software modules. This documentation is used to construct a representation of the hardware and software of the robot on a map, based on Self Organizing Map (SOM), similar to the human somatosensory map. This map structure can be used to quickly retrieve information semantically related (Honkela et al., 1997). From this map we can use different approaches to ascend to a higher level of abstraction. In particular, the approach used in this paper involves a simple association be-

tween labels arising from data and ontology entities, trying to get the expressiveness with a enormous knowledge based on common sense using Cyc (see [www.opencyc.org](http://www.opencyc.org)).

## The Introspection Architecture System

Our approach to introspection is based on self observation and communication. Figure 1 shows the proposed architecture. Considering the definition of Sloman, self observation is what the robot should do in order to build, represent and understand its internal state. In particular it is necessary to have a set of sub-systems dedicated to make a snapshot of the Nao robot state. Some systems are supplied by Nao system software, while some others are developed ad-hoc. The data obtained are used to build a rich state representation that should be supplied to an ontology that associates a meaning to the internal state. Our approach integrates static and dynamic information on robot operation.

Static information is related mainly to robot hardware parts and software modules, like hardware drivers, or modules that supplies some services like face tracking. But these parts can be active or not during robot operation, and their state is part of the robot state itself. A simple list of these parts can be difficult to manage. In order to obtain a manageable state representation we decided to develop a map that collects all the robot parts, and to highlight on this map all the parts that are involved in any robot operation. Such a map can be obtained using the information contained in the robot documentation that is rich of hardware and software details. Dynamic information is also represented on the map but they came from robot operation. When the robot is operating it is possible to highlight on the map the units corresponding to the active modules and the unit corresponding to the hand. This is a part of the robot state representation. According to figure 1 this Nao State Representation is supplied to a Semantic Bridge that analyzes the representation and gives as output a set of information (semantic labels) that are used to activate the right concepts on the ontology.

The Linguistic Level exploits these activations in order to perform a verbal interaction with the human user. In the present implementation the Semantic Bridge is constituted

Figure 1: The proposed architecture for introspection

by a set of labels.

### Self Observation

The Nao state representation is obtained by using the information in documentation, the list of processes running on Nao system, and the information from sensor input. The Self Observation module builds a representation of the internal state of the robot, mixing together the information related to the robot hardware and the information available about software modules running during robot operation. This representation should be rich enough to represent the perception of the robot body from sensors, to distinguish different kind of sensors, and also to describe the list of active processes that control the robot movements and any other useful state component. The robot documentation collects information about the robot hardware and software, so it is a good starting point for this kind of representation. In order to obtain a suitable document representation, useful for clustering, a sequence of standard pre-processing techniques were applied. A SOM (Kohonen, 1995) architecture has been used to cluster semantically related documents. The sensory input receives the visual information from the cameras and filters the input to select the most promising areas for the downstream tasks. Nao software platform supplies a list of processes available on the Nao system. These scripts are also mapped in the document SOM using a suitable set of keywords. Finally a third part of the Nao state is obtained using some custom scripts that output the list of processes running on the Nao system.

### The Semantic Bridge and Linguistic Level

The semantic bridge subsystem obtains a set of suitable labels from the Nao internal state representation. At present the implementation of the semantic bridge uses a look-up table that connects the map state images to the labels in the ontology concepts.

The Nao robot has an internal knowledge of its physical structure and functionalities. This knowledge can be exploited to support direct communication on the perception capabilities of the robot, and to describe his state to an

human interlocutor by using natural language. Moreover, modern semantic tools and introspection capability can be exploited together to improve and support direct communication on the robot perception mechanisms (Infantino et al., 2012; Augello et al., 2013).

The Cyc knowledge base (KB) has been used to code relations, concepts, constraints, and rules regarding the Nao robot domain. These concepts have been organized in order to fulfil the self-observation task.

The linguistic level is aimed at interpreting natural languages query given by the user. This level exploits a classical pattern-matching technique enhanced with Cyc ontology inference capability. This feature is obtained by transforming natural languages requests into symbolic queries, expressed in the ontology language. Such commands are forwarded to the ontology engine that computes the appropriate inferences and gives results in a symbolic form. The symbolic answers are then transformed by the linguistic module into natural language sentences that are finally shown to the user. The linguistic level has been implemented by using the A.L.I.C.E. web bot (see [www.alicebot.org](http://www.alicebot.org)).

## Abstract

This abstract summarises a model of route navigation inspired by the behaviour of ants presented fully in Baddeley et al. (2012). The ant's embodiment coupled with an innate scanning behaviour means that robust route navigation can be achieved by a parsimonious biologically plausible algorithm.

The ability of social insects to learn long foraging routes guided by visual information (Wehner, 2009) shows that robust spatial behaviour can be produced with limited neural resources (Chittka and Skorupski, 2011). As such, social insects have become an important model system for understanding the minimal cognitive requirements for navigation and, more generally those studying animal cognition using a bottom-up approach to the understanding of natural intelligence (Wehner, 2009, Shettleworth, 2010) while also providing inspiration for biomimetic engineers. Models of visual navigation that have been successful in replicating place homing are dominated by snapshot-type models where a single view of the world as memorized from the goal location is compared to the current view in order to drive a search for the goal (Cartwright and Collet, 1983; for review, see Möller and Vardy, 2006). Snapshot approaches only allow for navigation in the immediate vicinity of the goal however, and do not achieve robust route navigation over longer distances (Smith et al., 2007). Here we present an embodied parsimonious model of visually guided route learning that addresses these issues (Baddeley et al., 2012). By utilising the interaction of sensori-motor constraints and observed innate behaviours we show that it is possible to produce robust behaviour using a learnt holistic representation of a route. Furthermore, we show that the model captures the known properties of route navigation in desert ants.

Our navigation algorithm consists of two phases (see Baddeley et al., 2012, for details). The agent first traverses the route in 4cm steps with direction determined by a combination of noisy path integration (PI; true heading plus Gaussian noise, mean 0, s.d. 5°) and obstacle avoidance, during which the training views used to learn the route are experienced (a view is used after every 4cm step). In some experiments, a predefined learning walk is added to the start of the training path with training views taken every 2cm. To navigate, the agent visually scans the world by rotating on the spot through  $\pm 90^\circ$  of the current heading in  $1^\circ$  steps, behaviour similar to that observed in ants (P. Graham, *Personal Observation*). The most familiar direction during the scan is identified by inputting each view into an artificial neural network (ANN) trained to perform familiarity discrimination using the training views. Views are panoramic in azimuth and cover  $68^\circ$  of elevation above the horizon. Acuity is  $4^\circ$  meaning views are  $90 \times 17$ . The ANN is fully connected with  $90 \times 17$  (one per pixel) inputs and outputs and

no hidden layer. Weights are adjusted once per training view using an Infomax learning rule, with training views then discarded. The algorithm thus 'learns' routes after a single journey and memory load does not scale with route length. After training, the ANN outputs a familiarity score for each view input during a scan. Gaussian noise (mean 0, s.d.  $15^\circ$ ) is added to the direction associated with the most familiar view, a 10cm step is made in this direction, and the scanning routine repeats, until within 4cm of the goal or timed out.

We test our route navigation by learning a series of routes through visually cluttered environments consisting of objects distinguishable only as silhouettes against the sky. The model's performance is shown in figure 1. The model is able to learn idiosyncratic routes after a single training run (fig. 1A). As with ants, the routes show clear polarity and can only be traversed from start to goal. While successful for route navigation, if the agent misses the goal, it will typically continue in a direction similar to the last steps of the training route (fig. 1B) rather than search for it. To learn how to return to a specific goal location from nearby local surrounding regions, some ants perform a learning walk consisting of several loops out and back towards the goal when they first leave it. Adding such a walk to the training path means that when the agents nears or passes the goal, familiar directions are set by views experienced during the learning walk and draw the agent to the goal (fig. 1C). The model thus exhibits both place-search and route navigation with one mechanism. The model also learns multiple idiosyncratic routes to a goal (Fig. 1D-E). Here, three different routes are used but encoded within the same network which does not separate routes into distinct paths but stores all the information holistically. Given this performance, we believe our model represents the only detailed and complete model of insect route guidance to date.

Our approach is differentiated from previous attempts to understand route navigation in insects in several ways. 1) Navigation is independent of odometric or compass information. Unlike most snapshot-type models, training views are used as they are experienced, and are not rotated into common orientation before use. 2) The algorithm does not specify when or what to learn, but uses all views experienced during training. 3) Training views are not discrete waypoints. Previous route navigation algorithms navigate from one waypoint to another in a sequence, meaning one needs to know which waypoint is being used. Here, we do not navigate to each training view. Rather training views recall familiar directions not discrete places and are used to learn a holistic representation of the route; this representation says "What should I do?" not "Where am I?". This means that 4) navigation proceeds through a simple embodied strategy of rotating on the spot – a behaviour observed in navigating ants – and moving in the most familiar direction.

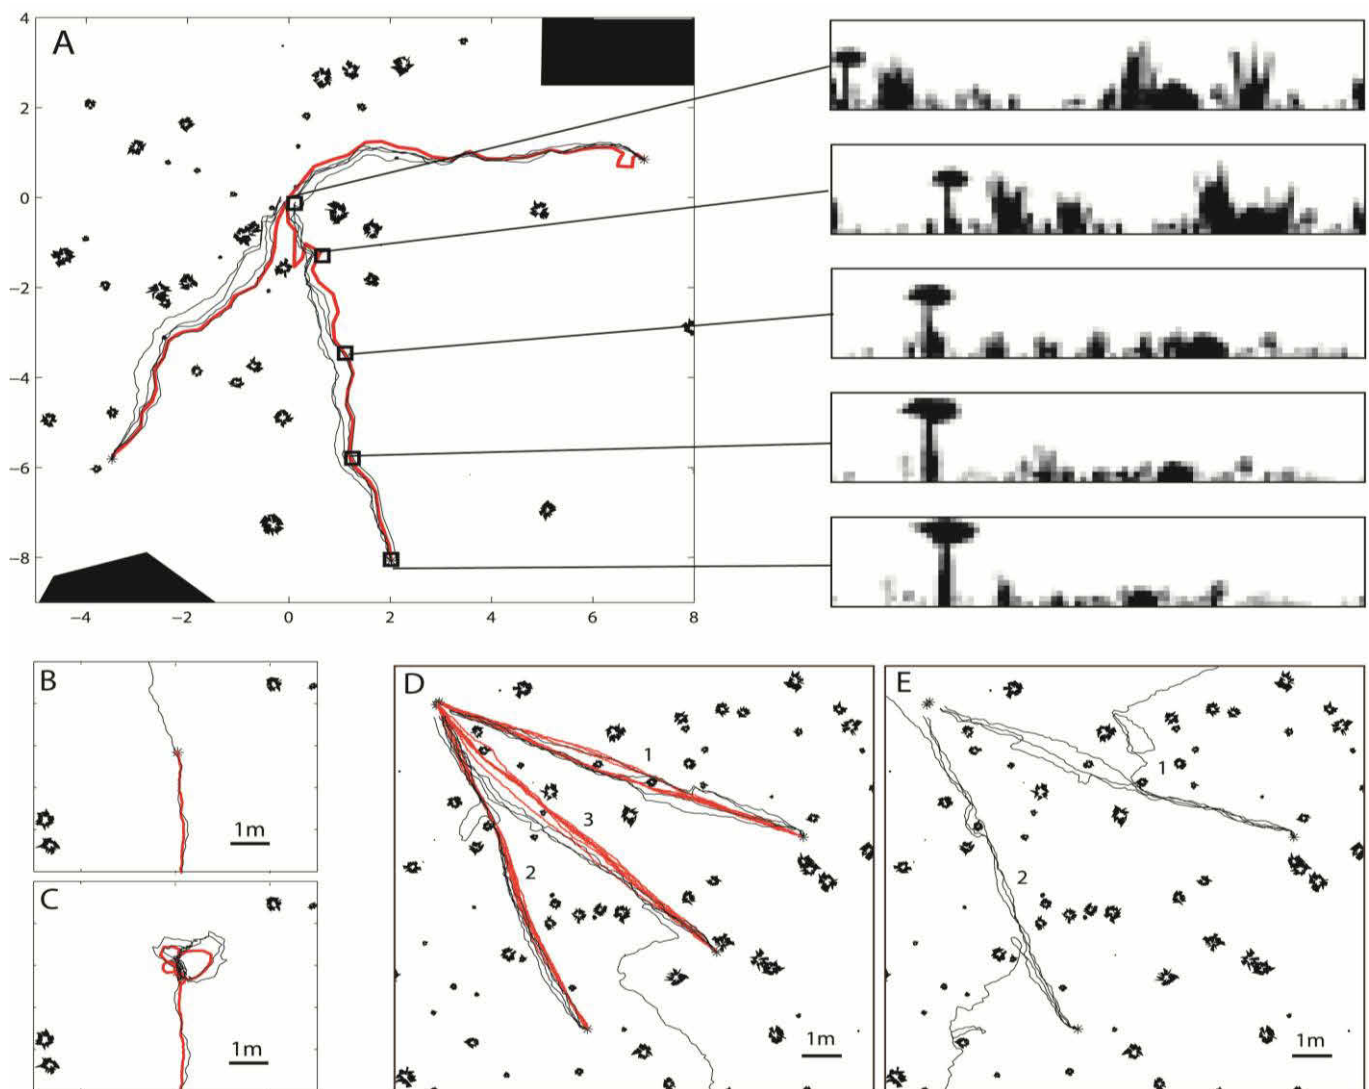

Figure 1: Route navigation with an embodied holistic model. The simulated world is viewed from above and is comprised mainly of small tussocks and a few larger more distant objects (trees and bushes). In all panels, red lines are training paths, black lines recapitulations. **A:** Successful return paths for three different routes. The panels to the right show example views covering  $360^\circ \times 68^\circ$  with  $4^\circ$  acuity from points along the training route (squares). **B-C:** Including learning walks prevents return paths from overshooting the goal. **B)** Without a learning walk the simulated ant overshoots and carries on in the direction it was heading as it approached the nest location. **C)** By including the views experienced during a learning walk the simulated ant, instead of overshooting, gets repeatedly drawn back to the location of the nest. **D-E:** Learning multiple routes. **D)** Route recapitulation performance (black lines) for each of three routes (red lines) that are learned with the same network. Testing of each of the routes is performed immediately following training on that route and prior to experience of other routes. Numbers by training routes show order in which routes were learnt. **E)** Performance on first two routes following learning of all routes, indicating that the route knowledge gained during the first two phases of learning is retained. Having learnt all 3 routes the network encodes 30m of route information.

### Abstract

In order to trigger an adaptive immune response, T cells move through lymph nodes searching for dendritic cells that carry antigens indicative of infection. We observe T cell movement in lymph nodes and implement those movement patterns as a search strategy in a team of simulated robots. We find that the distribution of step-sizes taken by T cells are best described by heavy-tailed (Lévy-like) distributions. Such distributions are characterized by many small steps and rare large steps. Our simulations show that heavy-tailed motion leads to dramatically faster search compared to Brownian motion, both in groups of T cells and in teams of robots. The mechanisms that cause heavy-tailed movement patterns in T cells are not fully understood. However, in robot simulations we find that heavy-tailed movement improves search speed whether that movement is caused by rules intrinsic to the robots or by adaptive response to extrinsic factors in the environment.

### Introduction

Biologically-inspired computation has a long history. Neural networks, genetic algorithms, and cellular automata are just a few well-known examples. In this study we observe immune cells searching within the three-dimensional space of mouse lymph nodes. We characterize T cell movement, demonstrate its effectiveness as a search strategy, and implement a similar search in simulated robots foraging for resources.

Robot teams can be used to perform real-world tasks such as surveying planetary surfaces and interplanetary space (Fink et al., 2005), land and sea mine clearance (Weber, 1995), pollution mapping by subsurface robots (Hu et al., 2011), and survivor location in hazardous environments (Birk and Carpin, 2006). The success of robot teams searching for resources in an unknown environment depends on the efficiency of the random search strategy employed.

### Biological Context

In order to mount an effective immune response, T cells must be activated in lymph nodes (Fig. 1). Activation occurs when a T cell discovers and interacts with a dendritic cell (DC) presenting a specific antigen. Antigens are markers that identify particular pathogens. Each T cell matches

a particular range of antigens. A DC presenting an antigen indicates that the corresponding pathogen has been encountered in the organism's tissues. If a T cell encounters a DC displaying cognate antigen then an immune response is triggered (Mackay et al., 2000).

To facilitate T cell activation, T cells and DCs interact within the T cell zone of lymph nodes (Fig. 1). The T cell zone is on the order of  $1\text{ mm}^3$  in the inguinal mouse lymph nodes we analyse. T cells and DCs are on the order of  $10\text{ }\mu\text{m}$  in diameter, so for each lymph node the T cell searches a space some  $10^8$  times its own volume. In secondary lymphoid organs, DCs usually comprise between 1% and 5% of the T cell zone's total cell population. Each T cell interacts with as many DCs as possible in order to maximize the probability of detecting a matching antigen (Mirsky et al., 2011). This imposes the need for efficient random search to mount an immune response.

Early response to infection depends on the rate at which DCs are discovered by T cells in the lymph node. The adaptive immune system is in an evolutionary arms race against an exponentially-growing pathogen population. That evolutionary pressure selects for efficient detection of, and response to, infection (Hedrick, 2004). Therefore we hypothesise that evolutionary pressure has produced an efficient mechanism for bringing T cells and DCs together, providing a model that can be used for random robotic search.

In this study, we use concepts derived from analysis of T cell search within lymph nodes to inform random robotic search. We identify the type of search used by T cells, then apply the observed three-dimensional search characteristics to a simple continuous space model. We simulate and characterize the performance of T cell inspired search strategies in robots using the iAnt robot system (Hecker et al., 2013). We found heavy-tailed search to be so effective for our simulated iAnts that we have begun incorporating it into the current multi-robot foraging algorithm. We find that T cells use a heavy tailed Lévy search and we show that this search strategy is more efficient than normally distributed random search.

Figure 1: Diagram of a lymph node where T cells search for DCs.

Figure 2: Image frame taken through two-photon microscopy of T cells (red and green) moving in the lymph node. The scale bar at the bottom of the image is 20 μm.

| Distribution | Formula                                                                      | Parameters            |
|--------------|------------------------------------------------------------------------------|-----------------------|
| Normal       | $\frac{e^{-\frac{(x-\mu)^2}{2\sigma^2}}}{\sigma\sqrt{2\pi}}$                 | $\sigma > 0, \mu > 0$ |
| Exponential  | $\frac{1}{\mu}e^{-\frac{x}{\mu}}$                                            | $\mu$                 |
| Log-normal   | $\frac{e^{-\frac{(\ln x - \mu)^2}{2\sigma^2}}}{x\sigma\sqrt{2\pi}}$          | $\sigma > 0, \mu$     |
| Gamma        | $\frac{1}{b^a\Gamma(a)}x^{a-1}e^{-\frac{x}{b}}$                              | $a, b$                |
| Power-law    | $\frac{1}{\sigma}\left(1 - k\frac{x-\theta}{\sigma}\right)^{-1-\frac{1}{k}}$ | $k, \sigma, \theta$   |

Table 1: Definitions and parameters for the five probability density functions used to model random motion.

## Stochastic Search

Search in 2- or 3-dimensional space is a common task in biological and engineered systems. Deterministic search strategies may be effective in relatively fixed environments where the distribution of search targets is known *a priori*. However, in environments where target distributions are unknown or change over time randomized search strategies are more effective (Stephens and Krebs, 1986; Acar et al., 2003).

Brownian motion is a common model of random walks. The turning angle between each step is drawn from a uniform distribution (Table 1, row 1).

Viswanathan et al. (2002), among others, described Lévy walks as a model for random walks that differs from classical Brownian motion. In that formulation, step lengths are drawn from a PDF over a power-law distribution. Power-law PDFs are scale-free and have heavy-tails with infinite variance. As a consequence, Lévy walks have many small steps and monotonically decreasing but non-zero probability of taking very large steps (or steps of any finite size). We use the Pareto (1895) formulation of the power law PDF (Table 1, row 5).

We define heavy-tailed distributions to be those with positive tails that approach zero less quickly than the exponentially-distributed PDF (the sub-exponential criteria, Bryson (1974)). Among many others, the log-normal (Table 1, row 3) and power-law distributions meet this criteria, whereas the normal and exponential distributions do not. We follow Shlesinger et al. (1999) in defining the heavy-tailed distribution of velocities (step lengths per time increment) as a *Lévy drive* and reserve Lévy walk for a heavy-tailed distribution of step-lengths with no time component.

Benhamou (2004) argues that Lévy walks are commonly misidentified and that the true picture is often of switching between travel phases from cluster to cluster and Brownian motion once a cluster is found. This pattern of search can be modelled by a correlated random walk (CRW) (Gillis, 1955;

Kareiva and Shigesada, 1983). CRWs are a class of random walks that incorporate non-uniform distributions in turning angle (Mårell et al., 2002).

### Related Robotics Work

Simulated robots have used Lévy walks in combination with chemotaxis-inspired gradient sensing (Nurzaman et al., 2009) and artificial potential fields (Sutantyo et al., 2010) to efficiently search unmapped spaces with range-limited sensors. In contrast we consider *free* Lévy drives in this study which do not allow long-range interactions between target and searcher.

In work related to our own, Van Dartel et al. (2004) evolved primitive neural controllers for agents foraging in a simulated world. They observed emergent Lévy walk patterns associated with increasing fitness, converging on parameters consistent with optimal foraging behaviour described by Viswanathan et al. (1999).

Harris et al. (2012) in their supplemental material describe computer simulation of Brownian motion and the generalized Lévy-walk search in a sphere. They report that the Lévy-walk was able to detect targets more efficiently than Brownian motion.

## Methods

### T Cell Observations

Lymph nodes were prepared according to the protocol described previously by Matheu et al. (2007). T cells were purified by nylon wool according to Allenspach et al. (2001) and labelled with one of two fluorescent dyes:  $1\text{ }\mu\text{M}$  (micromolar) Carboxyfluorescein diacetate succinimidyl ester (CFSE) or  $5\text{ }\mu\text{M}$  5-(and-6)-(((4-Chloromethyl) Benzoyl) Amino) Tetramethylrhodamine (CMTMR).  $5\text{ to }10 \times 10^6$  labelled T cells were injected intravenously into recipient mice. Fifteen to 18 hours later, after T cells migrated into lymph nodes, the inguinal lymph nodes were removed and recorded using two photon-imaging.

Imaging experiments were performed using a Biorad Radiance 2000 scanner mounted on an Olympus upright microscope with a chamber temperature of  $37^\circ\text{C}$ . Explanted lymph nodes were incubated with a  $37^\circ\text{C}$  solution of Dulbecco's Modified Eagle Medium (DMEM) bubbled with 95%  $\text{O}_2$  and 5%  $\text{CO}_2$  in order to preserve cell motility (Huang et al., 2007). T cell behaviour within a lymph node was monitored in the T cell area at a minimum of  $70\text{ }\mu\text{m}$  below the surface of the node. For 4D (3 spatial+1 time) analysis of T cell motility, multiple stacks in the z axis (z step =  $3\text{ }\mu\text{m}$ ) were acquired every 15-20 s (depending on the number of z stacks acquired) for 15-40 min, with an overall field thickness of  $40\text{--}60\text{ }\mu\text{m}$ .

Cell motility was analysed with Imaris 6.0 (Bitplane AG, Zurich, Switzerland). Tracks that lasted less than 3 time steps were removed from consideration. Tracks with total length or displacement from the start location less than

Figure 3: Example T cell track visualized from experiment data. Cell positions were captured every 14.93 seconds.

$17\text{ }\mu\text{m}$  over the course of the observation were assumed to be non-motile and discarded.

The point sequences generated by Imaris were used to create position vectors joining adjacent cell locations and the Euclidean norm for each vector was calculated. This provides a distribution of step sizes that were fit to probability distributions using Maximum Likelihood Estimation (MLE) described by Myung (2003).

The lab observations described were replicated seven times, resulting in 63,812 steps in 3,110 T cell tracks. The maximum velocity over all observations is  $1.9\text{ }\mu\text{m s}^{-1}$  with a mean of  $0.11\text{ }\mu\text{m s}^{-1}$ .

### Characterizing T Cell Search

Observed T cell population step sizes were fit to more than 50 PDFs. Of those distributions 5 PDFs were selected for further analysis: normal, log-normal, exponential, power-law and gamma. Harris et al. (2012) among others used normal and power-law PDFs to describe cell motion. Log-normal and exponential distributions are well known models of many biological processes. These four distributions form null hypotheses about the motion that we might expect to observe. The gamma probability density function is included because we found that, for several of the observations, it was the best model of the observed step-size distribution (Table 1).

In all cases, the bin sizes and binning methods were varied in order to reduce the effect of bin sizes on distribution fits. Adaptive binning rules described by Freedman and Diaconis (1981) were utilized along with various fixed bin sizes. Binning effects were not observed to be a factor in the fits.

Figure 4: Clusters of targets with searcher tracks. Undiscovered DCs are pink, discovered DCs are red. Each coloured track corresponds to the path followed by each of the 6 searchers. 100 clusters of 30 targets are shown.

The relative *goodness of fit* (GoF) of each PDF to empirical data was evaluated using the Kolmogorov-Smirnov, the Bayesian information criterion (BIC), described in and the Akaike information criterion (AIC), as well as with log-likelihood measures (Table 2). Anderson-Darling calculates the integral of the area between the empirical data and the PDF. The Kolmogorov-Smirnov test matches the mean and variance of the observed data to the PDF and tests for normality. AIC and BIC incorporate the number of parameters available in the PDF to be fit to the observed distribution into the GoF value. AIC and BIC measure the information lost by replacing the observed data with a model.

Controversy exists around the identification of power-law PDFs and associated claims of Lévy walk observation. Many data sets that were not generated by a power-law PDF can be fit to a power-law distribution (Reynolds, 2008). We use techniques developed by Clauset et al. (2009) to address the fitting problems unique to power-law distributions. Distributions were fit to data and goodness of fit calculations were made in MATLAB and Statistics Toolbox Release 2013a (The MathWorks, Inc., Natick, Massachusetts, United States. 2013).

In order to determine whether the distribution of step sizes observed in the total population was due to the distribution of step sizes across tracks or within tracks we used the method of Petrovskii et al. (2011). Each track was scaled by the mean step length of that track and the distribution of the scaled tracks compared to the original tracks. Since the distribution was preserved after tracks were scaled the distribution is due to intra-track step lengths rather than differences in track means.

## Simulation in a 3D domain

Our 3D simulation models the search space as a continuous unit sphere (Fig. 4). For these experiments we used  $m = 16,384$  targets divided into  $n$  clusters, giving a target detection density on the same order as that estimated for DCs in lymph nodes.

Searchers were considered to have discovered a target if they came within a parameterized distance  $\gamma$  of a target. Targets were only available for discovery once. Search steps are treated as discrete in a continuous space, so detection of targets is checked at the end of each step and not at intermediary points. This detection radius encompasses the possible role of chemical gradients and DC dendrites reaching out into the surrounding space. Both mechanisms could be modelled by increasing  $\gamma$ .

Brownian motion is modelled as a sequence of fixed step lengths with uncorrelated turning angles. This results in motion that in the aggregate consists of movements along a trajectory (perhaps containing multiple steps) which is uncorrelated over any sub-sequence of trajectories. This formulation satisfies properties of Brownian motion identified by Einstein (1905): that trajectory lengths are uncorrelated, and displacement from a starting location tends towards a normal distribution. We tested this conclusion by repeating our experiments with Brownian motion modelled by step sizes drawn from a normal distribution and found the same performance.

Paths corresponding to the log-normal, exponential, gamma and power-law distributions were created using the same procedure, except that the scaling radial length was drawn from a PDF in which the mean value  $\mu$  is equal to  $r$ . This allows search to make relatively long jumps while making most of the jumps closer to the fixed step size of the discrete random walk. The simulation was written in C++ and PDFs calculated using the BOOST C++ Libraries 1.53.0 (Austern, 2005).

## iAnt Robot System

iAnt robots (Hecker et al., 2012) implement ant-inspired algorithms that mimic colonies of seed-harvester ants using a combination of individual memory and pheromone trail to collect resources and carry them to a central nest. Robots are equipped with ultrasound sensors, compasses, and cameras (Fig. 5) mounted on the robots which enable them to search for and find resources placed in various configurations. The iAnt simulator replicates the movement and sensing capabilities of these robots. iAnt behaviour has several phases, including a random search phase. The parameters for this search are determined by a genetic algorithm (GA) which evolves simulated iAnts and produces a strategy for the physical robots to use in the real resource collection task. Targets were distributed into 32 piles of 32 tags.

Figure 5: Simulation of the physical iAnt robots. Grey dots are QR tags which are the target of search. Circles are robot locations. Blue circles indicate a robot that has found a tag and is returning to a central location. Green circles are robots engaged in search. The pink line is a pheromone trail. Each of the 6 iAnts we have built is run by an on-board iPhone.

**Adaptive correlated random walk (ACRW)** In previous implementations, robots explored an experimental area using a random walk with fixed step size and a direction drawn from a normal distribution (Table 1, row 1). The standard deviation  $\sigma$  determines how correlated each step is with the previous step. In the ACRW  $\sigma$  varies depending on the observed density of targets in the search location. The search pattern therefore depends on the local density of targets observed by the robot.

We implemented five search strategies in simulation and compared them to one another: Brownian motion, a Lévy-like (log-normal) strategy, correlated log-normal, and two adaptive correlated random walks. The original ACRW used normally distributed step sizes; we compare that to an adaptive walk with log-normal distributed step sizes. With the exception of Brownian motion, each strategy has different parameters that are evolved by the iAnt genetic algorithm (GA). Log-normal search uses an evolved standard deviation to parameterize its log-normal step length distribution. Correlated log-normal search includes a second evolved standard deviation to parameterize a normal distribution of step angles. The adaptive correlated normal search has two evolved parameters that adapt step angle correlation, depending on whether robots have previously found resources or followed a pheromone trail. Adaptive correlated log-normal search uses the same two parameters to adapt step angle, as well as a third parameter to control the distribution of step lengths.

Figure 6: PDFs fit to a probability histogram of T cell velocities taken from all 7 experiments. Qualitatively and quantitatively the log-normal and gamma distributions fit the data more closely than the normal distribution. The normal distribution underpredicts how often large velocities occur, the log-normal distribution slightly underpredicts the number of small values, while the gamma distribution slightly underpredicts the number of large values.

| Distribution | AICc ( $\times 10^5$ ) | Log-likelihood ( $\times 10^4$ ) | K-S             | Relative AICc |
|--------------|------------------------|----------------------------------|-----------------|---------------|
| Normal       | -1.29                  | -6.49                            | 0.12, $p = 0$   | 0.84          |
| Exponential  | -1.52                  | -7.60                            | 0.1413, $p = 0$ | 0.94          |
| Log-normal   | -1.59                  | -7.95                            | 0.0748, $p = 0$ | 0.97          |
| Gamma        | -1.62                  | -8.11                            | 0.0460, $p = 0$ | 0.98          |
| Power-Law    | -1.64                  | -8.23                            | 0.0888, $p = 0$ | 1.0           |

Table 2: Goodness of fit using Akaike information criterion with finite size correction (AICc), Kolmogorov-Smirnov (K-S), and Log-likelihood tests.

## Results

### Characterizing T Cell Search

In all cases BIC and AIC measures were in agreement so only AIC results are presented.

We first asked what type of PDF best describes the type of T cell search occurring in lymph nodes. Table 2 shows the relative goodness of fit for each of the PDFs we considered when applied to the entire data set of T cell velocities. The K-S test rejects all the candidates as acceptable fits (small  $p$ -values), this is mostly due to the very large number of data points being fit. As the number of points increases, the tolerance for any deviation from the ideal analytic curve is reduced. Since empirical data necessarily differs from the ideal parametric PDF, with enough data points no distribution will be accepted as a fit to the data (i.e. fail to reject  $H_0$  that the observed data and proposed model come from the same PDF). As a result we use the AICc and log-likelihood methods to evaluate how well the distributions fit our data. Lower values for the three tests indicate better fits.

Considering the seven observational experiments sepa-

| Distribution | Parameters                                                                 |
|--------------|----------------------------------------------------------------------------|
| Normal       | mean ( $\mu$ ) = 0.11, sigma ( $\sigma$ ) = 0.08                           |
| Exponential  | mean ( $\mu$ ) = 0.1118                                                    |
| Log-normal   | log location ( $\mu$ ) = -2.5024, log scale( $\sigma$ ) = 0.84             |
| Gamma        | Shape (a) = 1.75, Scale (b) = 0.06                                         |
| Power-Law    | Shape (k) = -0.05, Scale ( $\sigma$ ) = 0.1, Threshold ( $\theta$ ) = 0.01 |

Table 3: Maximum likelihood parameter estimates.

Figure 7: Comparison of search strategy performance across changes in target distribution. The y-axis is time for 6 searchers to find 1,000 targets. Bar = median, circle = mean.

rately resulted in power-law, log-normal and the gamma distributions being the top three fits, with one exception where the normal distribution ranked third in a single experiment. While all distributions are rejected by the Kolmogorov-Schmirnov test when fit to all the data, heavy-tailed distributions fit to individual experiments are not rejected. This leads us to believe that the data are not perfectly represented by any particular distribution, though our analysis shows that the heavy-tailed distributions are the best models to describe T cell movement in lymph nodes.

### 3D Performance

We then modelled search efficiency to test the search performance of heavy-tailed distributions and normal distributions using the model shown in Fig. 4. Evaluation of the search performance in simulation reinforces the functional similarity between the two heavy-tailed distributions (log-normal and power-law) and the gamma distribution which was parameterized to take on a heavy-tailed form. The two non-heavy-tailed search strategies (exponential and normal) failed to discover targets as quickly as the heavy-tailed search strategies (Fig. 7). Distribution parameters for the simulation were taken from those observed in PDFs fit to T cell motion (Table 3).

Heavy-tailed search did better than its competitors in finding targets quickly and with lower variance. Heavy-tailed search continues to find targets quickly when targets are

Figure 8: Comparison of search strategies in the iAnt simulator. We compare Brownian search, log-normal search, and adaptive correlated random walk strategies. While the heavy-tailed log-normal search performs better than Brownian search the correlated random walk is able to collect 25% more QR tags, and the adaptive correlated walks are able to collect 42% more tags in the same period.

highly clustered and separated by voids because they are able to cover gaps in less time than Brownian motion can. The cost heavy-tailed distributions pay is that they do not search the area they are in as exhaustively as Brownian motion. If a Brownian searcher happened to start near a cluster of targets it discovered many of those targets. If clusters were further removed from the searcher's initial placement then Brownian motion would have difficulty reaching the nearest cluster in a reasonable amount of time, this results in the high variance seen in Fig. 7. Heavy-tailed search is not as susceptible to the initial distribution because the rare but relatively large step sizes allow distances to be covered quickly so initial conditions have less impact on search success. Results presented are for 6 searchers but we observed similar behaviour for single searcher experiments.

### iAnt Performance

We then applied the heavy-tailed step size to the iANT robot simulation system for robotic target search. Performance of Brownian, log-normal, correlated log-normal, adaptive correlated Brownian and adaptive correlated log-normal search is shown in Fig. 8. The log-normal distribution was chosen to represent the heavy-tailed distributions due to simplicity of implementation and easy comparison to the normal distribution of Brownian motion.

The results for the 2D iAnt simulation were consistent with those from the 3D simulation. The heavy-tailed log-normal search outperformed Brownian motion in the iAnts. The adaptive strategies correspond to correlated random walks in which the correlation between step angles de-

depends on the target environment observed by the robots. Both adaptive search strategies significantly outperformed the non-adaptive algorithms. Robots using log-normal adaptive search collected more resources compared to robots using adaptive Brownian search. This difference is small but statistically significant:  $n = 198$ ,  $9.8\%$ ,  $p < 0.001$ .

The observed Lévy-walk pattern of step-sizes produced by the iAnt simulation performing the adaptive Brownian correlated walk are heavy-tailed.

## Discussion

We find that T cell movement in lymph nodes is better characterized by three different heavy-tailed distributions, power-law, log-normal and gamma than by exponential or Brownian motion (Fig. 6). Brownian and exponential distributions have commonly been used to model many processes in biology, economics, and physics (Mitzenmacher, 2004); however more recently, biological movement, including T cell movement through brain tissue (Harris et al., 2012), has been described by Lévy walks. Our results agree with previous studies showing that many biological systems adopt heavy tailed motion strategies, but do not follow an ideal power-law distribution of step sizes.

We have demonstrated that heavy-tailed distributions fit T cell motion in lymph nodes well, and are effective search strategies. Two of those heavy-tailed distributions are the log-normal and power-law distributions; Mitzenmacher (2004) discusses the history of debate across many fields and at many times regarding whether the lognormal or power-law distributions best model various phenomena. The heavy-tailed search strategies we simulated showed similar performance characteristics to one another. In that sense at least the particular distribution does not appear to matter as long as it allows a mixture of long steps with low likelihood and many small steps with high probability.

Our lymph node simulations show that the three heavy-tailed distributions search equally well, and much better than Brownian motion (Fig. 7). This is true of search for DCs distributed in a wide range of cluster densities. Thus the question of whether step size distributions are precisely power-law may not be relevant for determining the efficiency of the search process.

Viswanathan et al. (1999) shows that Lévy walks are optimal search when target clusters are sparse and targets are relatively slow compared to searchers. Numerous papers identified Lévy walks in biological data sets. Recently T cells have been found to perform Lévy walks in mouse brains as a response to parasitic infection (Harris et al. (2012)).

Using the iANT simulation, we found that walks that adapt to detected resources perform much better than simpler non-adaptive walks. Log-normal adaptive search performed only slightly better than Brownian adaptive search. However, we note that the observed distribution of steps sizes in the Brownian ACRW is also heavy-tailed. The com-

bination of step directions that are correlated over time (an intrinsic property of the robots), and adaptation to detected resources (an extrinsic property of the environment) results in an effective adaptive search.

In robots, the heavy tailed distributions caused by walks that adapt to environmental signals are much more effective than parametric heavy-tailed walks that are not adaptive. However adaptive walks may appear to have a heavy-tailed distribution of step lengths. It is currently unknown whether T cells might use the same adaptation strategy to respond to their environment within the lymph node. The lymph node has a complex structure, which includes the fibroblastic reticular cell (FRC) network (Chai et al., 2013). The FRC scaffold appears to serve multiple functions, but T cells have been observed, at times, to move along the FRC (Bajénoff et al., 2006). If the FRC network partially governs the motion of T cells, it would be considered an extrinsic factor as opposed to intrinsic cellular motion. Since T cells, and the lymph node in which they search for DCs, are here considered as part of the same system, we do not distinguish between intracellular and extracellular factors controlling the pattern of search. Therefore, even though extrinsic factors can shape T cell motion in vivo, our study doesn't discriminate whether T cells adapt their walks according to environmental cues in the lymph node. However this work suggests that as a hypothesis worth exploring.

In conclusion, our observations of T cell motion provided inspiration for efficient search in our robot systems and conversely observation of search in those robot systems has provided insight into the possible advantages that search pattern may provide to the immune system.

## Abstract

Autonomous robot road following has been widely investigated since the early 1980s and, whilst much progress has been shown, there is still no system which displays 100% generality across all types of problem. This work shows a novel approach to the problem, using the methodology of Evolutionary Robotics to facilitate the autonomous emergence of flexible, robust and general behaviours. One of the unique aspects of this approach is to encourage the evolution of a dynamic strategy of colour perception: facilitating the combination of different channels of the colour space to perceive contrast across a range of scenes where this would otherwise be impossible. The results described herein demonstrate the capability of this methodology to produce controllers capable of generalising across a broad range of road shapes to which the agents have not been previously exposed. They also vindicate the effectiveness of a dynamic colour perception strategy, enabling the controllers to perceive contrast in a challenging variety of situations.

## Introduction

In the realm of autonomous vehicles, road following, i.e., the ability to detect and traverse a road surface without straying from the boundaries, is clearly an important problem. As such, it has received much attention from artificial intelligence and autonomous robotics researchers over the last thirty years (Dickmanns, 2002).

The earlier attempts employed hand-crafted controllers focusing on roads that are clearly demarcated and delineated (e.g., those that have either white lines or a clear high contrast delineation between the road and non-road surfaces, see Wallace et al., 1986; Waxman, 1985; Turk et al., 1988; Kuan et al., 1988; Dickinson and Davis, 1988). The general thrust of these approaches is to establish some sort of model based on the *a priori* assumption that the agent is already situated on the road, and by sampling its sensory information accordingly. This model is then maintained by monitoring prominent road features such as edges and lane demarcations. In order to improve the flexibility and the capability of a solution to follow more road types, later research looked at roads which have no clear demarcation, have amorphous or unclear delineation of the road edges

and have low contrast between the road and the background surface, and are subject to changing road conditions due to e.g., shadows or reflections (see Crisman and Thorpe, 1988; Kluge and Thorpe, 1990). To further address this problem, researchers started to investigate more adaptive, learning and connectionist based, rather than hand-crafted approaches (see Jochem et al., 1993; Pomerleau, 1997; Dickmanns, 2002). Recent success in this field has also been gained by combining these approaches with higher level, more complex models and reasoning, facilitated by the increase in available computing power over the last decade and spurred by high profile involvement from the military and commercial sectors (see Chen and Tsai, 1997; Aufrere et al., 2000; Urmson et al., 2008). Most recent approaches to the road following problem then, range from these complex, high-level models updated from multiple sensory sources and requiring significant computational power, to more simple, reactive and robust systems with lower model complexity and hence computational requirements (see Katramados et al., 2009; Ososinski and Labrosse, 2012).

The road following problem, in common with many others, has at its root a strong visual perception and feature extraction component. One of the problems in such visual discrimination tasks is a method of processing the input images in such a way as to reduce environmental distractions (in this case for example, those arising from shadows or reflections) so as to allow extraction of the features relevant to the problem, and to show clear contrast between the features to be extracted. One such technique could be to examine and combine different representational components of the image when transformed into colour spaces that separate luminosity (brightness) information from chrominance (colour) information. This can allow, for example, the efficient removal of shadows and effective dimensionality reduction of the problem by combining the remaining colour components in ratios that provide good performance over a range of possible scenes (see Woodland and Labrosse, 2005; Benedek and Szirányi, 2007; Finlayson et al., 2006).

However, it should be obvious that a fixed combination of colour components will never be able to show good con-

trast for all possible road following scenarios: we may well encounter scenes for which a broadly good combination of colour components actually shows very little contrast due to the nature of the colours represented in the scene. One solution to this problem may be to examine multiple components of the colour space simultaneously, dynamically choosing only those components (or combinations of components) that yield high contrast. However, for systems where input informational throughput may be limited such as low power embedded systems, or those using neural networks (i.e., where dimensionality reduction is necessary), it will not be possible to appraise all of this information concurrently. Similarly, there may be colour channels which yield very high contrast within the image, but not amongst the features that are relevant to the particular problem at hand. It should be clear then, that a method of dynamically combining various components of colour spaces in a way which aids feature detection by removing unwanted artefacts and increasing the contrast available between the relevant features for extraction is required for optimal performance of such visual perception and discrimination tasks.

With that in mind, we propose a solution to the road following problem using artificial neural network controllers synthesised by evolutionary computation techniques. We illustrate a system that is capable of successfully navigating roads in a variety of distinct simulated environments based on visual information in an integrated action-perception loop where the neural mechanisms that govern perception (identification of the road features) and action (motor activations and changes in colour perception) are not only tightly coupled, but are one and the same. In this study, we examine the combination of the standard RGB colour space components to increase contrast between the desired features, under the assumption that a similar process could be used with components of other colour spaces (that better separate luminance from chrominance) to augment this aim, and to reduce disturbances caused by shadow or reflections. We analyse how a system of dynamic colour perception contributes to the overall road-following effectiveness of the controllers and we show that without this adjunct to perception, the agent would be unable to solve all of the road following tasks presented in this simulated environment.

In summary then, the main objective of this study is to apply evolutionary robotics to the road following problem to produce a solution which will coordinate vision and action in a single, unified sensory-motor controller. Further, we aim to show that a dynamic method of dimensionality reduction, arrived at in tandem with the road following behaviour, will prove beneficial in solving the problem at hand. The evolved agents are capable of developing a general strategy for staying on poorly demarcated and delineated roads based on single camera visual input. Moreover, they are also able to dynamically adjust their colour perception, in real time, to increase the efficacy of road following in environments with

Figure 1: Pioneer robot

different or changing colour properties.

## The Robot and the Simulation Environment

A simulated robot is required to navigate various types of road using visual input. Our simulation models a Pioneer 3-AT 4-wheeled skid steer all terrain research robot as shown in Fig. 1. The simulation also comprises a 3D model of an environment, rendered using OpenGL (<http://www.opengl.org>) that provides the sensory information that the robot perceives through its camera. This environment contains only 3 visual components: a tiled textured horizontal plane on which the robot travels (the ground), a textured deviated surface rendered on this plane (the road), and a sky-box to provide the illusion of sky.

The virtual camera renders the 3D scene from the point of view of a camera mounted on top of the virtual robot. It is configured to have a frustum representative of real-world cameras that may be used to capture the scene. For final evolution to produce effective solutions, this would need to match exactly the specific camera being used. As this had not been chosen at the time of evolution, representative values were used with the understanding that changing the frustum would not significantly affect the results and that we are showing that the general concept of using camera images in this way is sound.

The visual input for the robot's controller is generated by significantly reducing the resolution of each camera image. Our simulated camera renders images at  $250 \times 200$  pixels. We overlaid a  $5 \times 5$  grid on each image, with each square grid covering 2000 pixels. The robot sensory input is made of 25 numerical values generated as follows. For each grid square, a mean value for each colour component is calculated by summing red, green, and blue components of each pixel within this square separately, then dividing by the total number of pixels residing in this grid square. In this way we have 3 values per grid square corresponding to the contributions of red, green and blue elements in the image. We then combine these components by multiplying each by  $\alpha$ ,  $\beta$ , and  $\gamma$  respectively, and then summing to produce a final single numeric value for each square.  $\alpha$ ,  $\beta$ , and  $\gamma$  are floats in  $[0, 1]$  generated by the robot controller at each time step. They are normalised so they sum to 1 hence they represent the ratios in which the red, green, and blue channels should be mixed

Figure 2: The neural network. The lines indicate the efferent connections for only one neuron of each layer. Each hidden neuron receives an afferent connection from each input neuron and from each hidden neuron, including a self-connection. Each output neuron receives an afferent connection from each hidden neuron.

respectively. As pixel colour values are in the range 0-255, we then divide by 255 to scale this value between 0 and 1.

### Controller and the Evolutionary Algorithm

The robot controller is composed of a continuous time recurrent neural network (CTRNN) of 25 visual input neurons, 6 inter-neurons, and 7 output neurons (see Beer and Gallagher, 1992). The structure of the network is shown in Fig. 2. The states of the output neurons are used to control the speed of the left and right wheels as explained later, and they define the ratios for colour mixing. The values of sensory, internal, and output neurons are updated using equations 1, 2, and 3.

$$y_i = gI_i; \text{ for } i \in \{1, \dots, 25\}; \quad (1)$$

$$\tau_i \dot{y}_i = -y_i + \sum_{j=1}^{31} \omega_{ji} \sigma(y_j + \beta_j); \text{ for } i = \{26, \dots, 31\}; \quad (2)$$

$$y_i = \sum_{j=12}^{15} \omega_{ji} \sigma(y_j + \beta_j); \text{ for } i = \{32, \dots, 38\}; \quad (3)$$

with  $\sigma(x) = (1 + e^{-x})^{-1}$ . In these equations, using terms derived from an analogy with real neurons,  $y_i$  represents the cell potential,  $\tau_i$  the decay constant,  $g$  is a gain factor,  $I_i$  with  $i = \{1, \dots, 11\}$  is the activation of the  $i^{th}$  sensor neuron,  $\omega_{ji}$  the strength of the synaptic connection from neuron  $j$  to neuron  $i$ ,  $\beta_j$  the bias term,  $\sigma(y_j + \beta_j)$  the firing rate (hereafter,  $f_i$ ). All sensory neurons share the same bias ( $\beta^I$ ), and the same holds for all motor neurons ( $\beta^O$ ).  $\tau_i$  and  $\beta_i$  with  $i = \{26, \dots, 31\}$ ,  $\beta^I$ ,  $\beta^O$ , all the network connection weights  $\omega_{ij}$ , and  $g$  are genetically specified networks' parameters. At each time step, the output of the left motor is  $M^L = f_{33} - f_{32}$ , and the right motor is  $M^R = f_{35} - f_{34}$ , with  $M_L, M_R \in [-1, 1]$ . The firing rates  $f_{36}, f_{37}, f_{38}$  are

Figure 3: Road tile construction and circle approximation

normalised such that  $\alpha + \beta + \gamma = 1$ . Cell potentials are set to 0 when the network is initialised or reset, and equation 2 is integrated using the forward Euler method with an integration time step  $\Delta T = 0.2$ .

A simple evolutionary algorithm using linear ranking is employed to set the parameters of the networks (Goldberg, 1989). The population contains 60 genotypes. Generations following the first one are produced by a combination of selection with elitism, recombination, and mutation. For each new generation, the three highest scoring individuals (“the elite”) from the previous generation are retained unchanged. The remainder of the new population is generated by fitness-proportional selection from the 30 best individuals of the old population. Each genotype is a vector comprising 243 real values (228 connections, 6 decay constants, 8 bias terms, and a gain factor). Initially, a random population of vectors is generated by initialising each component of each genotype to values chosen uniformly random from the range [0,1]. New genotypes, except “the elite”, are produced by applying recombination and mutation. Each new genotype has a 0.3 probability of being created by combining the genetic material of two parents. During recombination, one crossover point is selected. Genes from the beginning of the genotype to the crossover point are copied from one parent, the other genes are copied from the second parent. Mutation entails that a random Gaussian offset is applied to each real-valued vector component encoded in the genotype, with a probability of 0.05. The mean of the Gaussian is 0, and its standard deviation is 0.1. All vector component values are constrained to remain within the range [0,1].

### The visual scene

Textures that represent real world scenarios were chosen for the road and ground surfaces from the plethora available at the multitude of free texture resources on the internet. In order to simulate roads with amorphous nondescript edges, the edges of road textures were manually faded out using noisy paintbrush tools in image manipulation software, and then alpha-blended with the underlying ground texture.

We devised three complementary scenes, each of which featured only two of the three colour components (red, green and blue). The third component is randomly varied with noise, and hence unable to contribute to the final contrast between road and background visible in the scene. Giving

this randomly varied colour component strong weight in the colour combination would actively detract from the structured contrast visible between road and non road surfaces. In this way, the agent has to choose—by appropriately setting  $\alpha$ ,  $\beta$ , and  $\gamma$  for each environment—the colour components which assist in solving the problem, and disregard those that do not show the pattern that is being sought. This random colour variation was first undertaken at the pixel level, but later reimplemented to occur at the grid average level. In this way, with any static (i.e., not changing with respect to the environmental features) selection of colour combination there would always be one scene in which the controller was unable to detect any contrast. In addition, as there was a requirement that the agents evolve a general strategy that was able to cope with the road surface being both brighter (having higher values) than the background, and vice versa, scenes were carefully devised with the properties shown in Table 1. As long as the differences between the higher and lower values were kept constant, this should result in the following attributes. In 3 colour grey scale, all of the scenes would show no contrast between the road and non road surfaces. By choosing a single colour component, the agent would see positive contrast for the road in one scene, negative in another, and no contrast in the third. By choosing to combine two fixed colour components, the results would be the same. With this configuration, the only means by which the agent can successfully navigate all three scenes, and hence score maximum fitness, is by changing which colour components are examined between or during trials.

Each agent is evaluated against 6 different environments: two road shapes (one starting with a left bend, the other with a right bend) for each of the 3 colour scenes. At each generation, 6 different road shapes are generated using the following algorithm. First, a single square road tile is placed at the centre point of the ground plane at a world relative heading of  $0^\circ$ . A random angle is then chosen between two bounds (initially  $\pm 20^\circ$ ) and a centre point coordinate position is calculated for the new tile by applying basic trigonometry to translate it forward by 0.75 times the size of the road tile along this new angle. The new tile is then placed at this position and rotated by the angle, as shown in 3. This process is repeated for the number of road tiles required (in our experiment, 20) with the centre point position and total angle of each road tile stored for later use. In rendering, only the

angles are required: each road tile is rotated by, and translated along, this angle by OpenGL.

## The Fitness Function

All of the individuals in a population are evaluated against the same 6 environments to yield a proper comparison of the agent's performance, and new random road shapes were generated for each generation to expose them to as wide a variety of road following scenarios as possible. At the beginning of each trial ( $e$ ), the robots are placed at the start of the road at a random orientation between  $\pm 30^\circ$ .

The fitness function used in this approach is heavily inspired by that found in (Suzuki et al., 2005). This is a function which rewards forward progress of the robot, and is calculated and tallied at each time step based on the left ( $S_l$ ) and right ( $S_r$ ) wheel speeds, and the naïve straight-line distance reward applied at the end of the trial. The distance from the starting point to the final agent position is calculated as a percentage of the distance from the starting point to the end point of the road. This is multiplied by a reward factor and added to the fitness to further encourage the agent to reach the end of the road. There are situations however where this strategy will be counter-productive: e.g., when a road curves round so that the end point is closer to the start point than other positions on the road where the trial might terminate. However, it was concluded that with our random strategy of road building, such occurrences are rare enough not to adversely affect the system.

To combat the behaviour of a robot travelling in tight circles at the start point in order to “game” the fitness function without traversing any of the road, a penalty was added, such that the final fitness is halved if the agent remains on the starting road tile at the end of the trial. Furthermore, to encourage even more strongly the robot to avoid leaving the confines of the road, the fitness is multiplied by a factor of 1.2 if the trial was not terminated by a failed road bounds check. This serves to make a clear distinction between behaviours where the robot gets most of the way down the road, but leaves the road at the very end of the trial, and where the robot reaches the end of the road without doing so. Therefore, the final fitness ( $F$ ) for each genotype is calculated as:

$$F = \frac{1}{E} \sum_{e=0}^E f_e; \quad (4)$$

$$f_e = \eta \lambda \left( \frac{1}{T} \sum_{t=0}^{T'} g(S_l, S_r, t) + H \frac{D_a}{D_r} \right); \quad (5)$$

$$g(S_l, S_r, t) = (S_l^t + S_r^t) \left( 1 - \sqrt{\frac{|S_l^t - S_r^t|}{2 \times S_{max}}} \right); \quad (6)$$

where  $E = 6$  is the number of evaluations or trials per genotype,  $\eta = 0.5$  if the robot remains on the first road tile at the

Table 1: Table showing road scene properties. H refers to higher values, L refers to lower values.

|         | Red       | Green     | Blue      |
|---------|-----------|-----------|-----------|
| Scene 1 | Noise     | L on road | H on road |
| Scene 2 | H on road | Noise     | L on road |
| Scene 3 | L on road | H on road | Noise     |

end of the trial, otherwise  $\eta = 1.0$ ;  $\lambda = 1.2$  if the robot does not leave the road during the trial, otherwise  $\lambda = 1.0$ ;  $T$  is the maximum number of time steps in a trial (180 for these experiments);  $T'$  is the number of time steps experienced by the agent during this trial (for example, 100 where the trial is terminated after 100 time steps due to the robot leaving the road);  $D_a$  is the straight line distance from the start point to the final agent position at the end of the trial and  $D_r$  is the straight line distance from the start point to the centre of the final road tile;  $H = 1000$  is a constant,  $S_{max}$  being the maximum allowable wheel speed setting, in this case 300.

It should be noted that this fitness function makes no mention of the road, and the requirement to stay within its bounds. Rather, the trial is stopped prematurely when a robot leaves the road surface, so maximum fitness is only available to those agents that are capable of staying on the road throughout the full duration of the trial. To check whether a robot is on the road, we used the following criteria. The road is treated as a series of overlapping circles rather than squares, as shown in Fig. 3. By checking if the centre of the robot is further away from a centre point than the circle approximation radius, we can tell if it lies inside or outside of this circle.

## Results

Our objective is to synthesise controllers for autonomous robots required to visually navigate road surfaces without straying from the boundaries. We looked at roads which have unclear delineation of the edges, and situated in environments with different colour properties. The robots are required to dynamically combine—by appropriately setting  $\alpha$ ,  $\beta$ , and  $\gamma$  for each environment— various components of the colour spaces in order to detect road edges and to distinguish the road from the background.

Ten evolutionary runs, each using a different random initialisation were carried out for 2000 generations. Two evolutionary runs managed to generate robots with sufficiently high fitness to indicate that they are capable of successfully navigating all the three road scenes. The other eight runs produced only sub-optimal solutions. Due to the nature of the evolutionary process and fitness function, we cannot guarantee that the individuals with the highest fitness are those that have evolved the most robust general strategies. It is likely, in fact, that these fitness values actually represent the agents that are the “luckiest” with respect to the random variation occurring in the simulation. To deduce which are actually the most useful evolved individuals, we further evaluated a selection of the most fit genotypes across a broader range of tests with systematic variation.

### Post-evaluation test I

In this test, a suite of road following scenarios is generated, with parameters pertaining to road shapes and starting angles systematically adjusted between them. The fittest in-

dividual from the 100 fittest generations from each of the two successful evolutionary runs are then evaluated against the same set of conditions, allowing for a side by side comparison of their general effectiveness at such road following tasks. Together, the evaluations performed in Test I represent an examination of the effectiveness of the agent’s road following behaviour across a set of scenarios to which it has not been exposed during evolution. This test, therefore, is performed with the aim of demonstrating the generality of the road following solution produced.

The evaluation scenarios are produced by varying the allowable bounds between which angles ( $\theta$ ) are chosen for road tile placement. Two roads are generated for each of the following four configurations (for a total of 8 scenarios), where  $\theta$  is a randomly selected angle that each tile is placed at, between the following bounds: 1)  $\pm 20^\circ$ , 2)  $\pm 30^\circ$ , 3)  $\pm 40^\circ$ , and 4)  $\pm 50^\circ$ . 6 further scenarios are generated using roads featuring smooth, contiguous bend, where the tile placement angle is kept constant and uniform between road tiles. Three constant tile placement angle values are used to generate these roads, corresponding to shallow, medium and sharp corners:  $20^\circ$ ,  $30^\circ$  and  $40^\circ$ . Angles greater than these resulted in unrealistic looking roads with tighter corners than one would reasonably expect such a road-following vehicle to be capable of traversing. To avoid the road looping back on itself to form a circle, the direction of the placement angle is reversed once the total corner angle reaches  $110^\circ$ . Two roads are generated for each of the three cornering angles described (for a total of 6 scenarios), the first starting with a left turn, the second with a right. Finally, we included a straight road without corners to ensure that agents are effective on simpler tasks.

All of the above 15 evaluation scenarios (8+6+1) are generated with a fixed tile width of 140cm. Visually, they are of mostly uniform but slightly variable width due to the noisy fading to background of the road edges, representing more ill-defined roads. The visible road width is therefore roughly 120cm, or roughly twice the diameter of our simulated robot. Accordingly, the circle radius used for the road bounds approximation test is 60cm. Each road has a total traversable length of 28m. Each of the above road shapes is rendered in the three colour and texture combinations used for evolution, resulting in 45 evaluation scenes. Individuals are evaluated against each scene 5 times with different initial robot headings. Relative to the first road tile placement angle, these are:  $-45^\circ$ ,  $-22.5^\circ$ ,  $0^\circ$ ,  $22.5^\circ$  and  $45^\circ$ . A trial is considered successful if the robot successfully navigates to the penultimate road tile, to take into account erratic behaviour caused by the road ending in the robot’s field of view. In unsuccessful trials, the percentage of navigable road tiles successfully traversed is recorded.

The results of test I are shown in Table 2. We can see from this table that the best performers succeed in getting to the end of the road in almost 85% of the 225 individual evalua-

Figure 4: The performance of the best 2 individuals broken down by test type. Red bars for agent 2-1834, green bars for agent 6-1802.

tions. This is no mean feat, as they not only contain a challenging set of environments featuring diverse colours and textures and some obtuse, complex road shapes with sharp turns and currently unnavigable portions of the road in the field of view, but also place robots at a variety of starting headings, pointing more towards the sides of the road than the agents were evolved to cope with. It is also clear that both successful evolutionary runs produced roughly equally effective solutions.

Using the best individual from each run, measured by success percent, we looked at how they fare with the different problem types. In Fig. 4 the percentage success is broken down across the three coloured road scenes, the different angled random and bendy roads, the straight road, and different starting headings. Comparing the three coloured scenes

from Fig. 4 we can see that both agents perform better on scene 2 than the others. This could be due to it being a slightly easier colour/texture combination than the others, with slightly more contrast visible between road and non-road areas, but it may also be down to random occurrences in the pattern of evolution. The agents likely evolve to solve a particular coloured scene first, before learning to change their colour perception—it might simply be that both agents happened to learn this scene first, and therefore had more “practice” completing it.

Comparing the performance across the set of random roads with different placement angles, we can see that the agent from run 2 (hereafter, Agent 2) showed roughly uniform performance of around 85% across all 4 road types. This serves to show that it has evolved a highly general, effective road following behaviour, with difference in success rates largely unaffected by the coarseness of random road angles. The difference in performance between Agent 2 and the agent from run 6 (hereafter, Agent 6), at the 20° random road is striking and somewhat surprising. One might expect both agents to perform very well on this road as it most closely resembles those that they were evolved against. We can also see that Agent 6’s performance drops off on the other angled roads, in contrast to Agent 2’s broadly uniform performance, suggesting that Agent 6 has specialised on the 20° road to the detriment of the more difficult roads, whilst Agent 2 represents the more general solution at these road types, though showing somewhat worse performance on the simpler challenges. Interestingly, this situation does appear to be reversed for straight roads, where Agent 2 significantly outperforms Agent 6.

We can also see that both agents perform uniformly in a very effective manner when started at angles in the range  $-22.5^\circ \leq \theta \leq 22.5^\circ$ , with a drop off in performance for both agents when placed at angles beyond this range. This can be explained by the fact that although, during evolution, all agents are placed at world relative heading of  $0^\circ$ , the random changes in road tile angles will subject them to situations where they are pointing up to  $20^\circ$  from the centre line of the road, and they have hence developed strategies to mitigate this situation. What is surprising is that both agents perform worse when the agent is facing far to the left ( $45^\circ$  starting angle) than when it is subjected to such angles in the opposite direction. There is no obvious reason for this from the attributes of the evolutionary trials, other than that, through random fluctuations, the agents may have been exposed to more left turns than right. In summary then, the agents complete these evaluation tests with high effectiveness and there is not a great deal to choose between them. Any significant out-performance by one agent in a test, is made up for, either by more generality of the other agent across more tests, or an out-performance of the other agent on a different test. This demonstrates therefore, the capability of the evolutionary process to produce effective agents that encapsulate a

Table 2: The top ten Test 1 performers

| Run-Gen. | Success % | Mean distance | Std. dev. |
|----------|-----------|---------------|-----------|

| 2-1808   | 80.44     | 7.95          | 16.80     |

general solution to the road following problem and are able to perform successfully across a wide variety of road types.

### Post-evaluation test II

Having analysed the generality and effectiveness of the road following behaviour in the previous test, it would also be useful to appraise the performance of the dynamic colour selection strategy evolved to show contrast in a variety of colour and texture scene combinations. To this end, the agent is exposed to 30 different scene texture combinations, representing all the possible combinations of the 6 textures shown in Fig. 5, using each texture as both road and ground surface. In order that the variance that we see in trial performance is due to the difference in texture combinations, rather than the varying performance across road shapes and starting angles, each agent is tested against roads generated using the same algorithm as that used in evolution to represent challenges of the sort with which the evolved agents should be most familiar. Similarly, rather than varying the starting heading of the agents on the road, each agent is started with a world relative heading of  $0^\circ$  as in evolution. 75 such roads are generated, and rendered in each of the 30 possible texture combinations, resulting in 2250 total evaluations per agent.

The results of this test, with respect to the different coloured scenes are plotted in Fig. 6. The labels for the bars of the histogram are in the form X/Y/Z where X is the agent number, Y is the first texture and Z is the second, according to the labels in Fig. 5. The bars are grouped by agent for each texture combination: the left bar being Agent 2, the right Agent 6, allowing direct comparison between the agents on different scenes. Each individual bar represents the mean percentage success rate for one agent across 150 trials: 75 road shapes with a particular road/ground texture combination, and the same 75 shapes with the reverse combination. The proportion of light and dark areas of each bar then represent the success rate for each of these individual reversals. For example, the bar labelled '2/B/T3' shows the performance of Agent 2, using a combination of 'Blue asphalt' and 'Asphalt 3' textures: the dark portion of the bar showing the success rate with 'Blue asphalt' road on 'Asphalt 3' ground, the light portion showing the reverse.

From the results of these tests, a few issues of note become apparent. Firstly it would appear that Agent 6 broadly outperforms Agent 2 in many of these trials. This likely suggests that Agent 6 has evolved a more general and effective

Figure 5: a) Grass (G), b) Sand (S); c) Blue asphalt (B); d) Asphalt 1 (T1); e) Asphalt 2 (T2); f) Asphalt 3 (T3)

Figure 6: Comparison of both agent's performance across a range of scenes.

strategy for dynamic colour perception than Agent 2, though it is also possible that this is in some part due to it having evolved road following strategies that are more specialised to the type of road shapes present in evolution. We can also see that, for the majority of texture combinations, there is at least one reversal of road and ground textures that an agent is able to solve to a high degree of efficiency, i.e., there is normally a coloured bar portion at least 0.4 units long, a percentage success rate of 80 % for this road/ground texture combination. There is also a problem visible here though, as a number of scenes can only be solved effectively in one of the two reversals of road and ground texture. This shows a lack of generalisation in the solution. There is however another problem visible in this data. There are some scenes in which no agent can reliably detect contrast and solve the road, for either reversal of road and ground textures. This effect is most pronounced for S/T2 texture combination and it is believed this is due to the colours in both textures being too similar for either combination of them to reveal significant contrast.

### Conclusion

In this work, we have demonstrated a technique, using evolutionary robotics, to design effective road-following behaviours in simulated agents controlled by artificial neural networks. We have shown that, by presenting a set of challenges with diverse colour properties, we can encourage the evolution of an autonomous, dynamic approach to colour perception which enables evolved agents to perceive contrast in scenes where this would otherwise be impossible.

The process of evolution seems to have produced a range of effective and general solutions, which encapsulate not only a robust solution to road following, but also a system of dynamic colour perception that is able to show contrast be-

tween road and non-road surfaces across a range of scenes where a constant grey-scale conversion would fail. Through performing a range of tests, we ascertained which of the solutions is more generally effective, irrespective of their fitness scores which could be influenced by luck. By breaking down the results of post-evaluation tests, we have shown that the most effective agents show good generality in their road following ability, being capable of following roads differing significantly from those that they were evolved against. Their generality with respect to starting angles is not as strong, but this is expected as they were not deliberately exposed to a representative selection of these when evolving.

In examining the most effective produced agents with respect to their colour and road perception abilities it becomes clear that there are a few limits to their generality. In some instances (though not in others) the agents are not able to follow both reversals of road and ground textures, suggesting an inability to deal with certain combinations of values demarcating the road, even when contrast is visible. We have suggested that this could be mitigated either with more diverse evolution scenes, or an extra output node to reverse the visual input values. Similarly, we believe the slightly reduced performance on a couple of scenes in post-evaluation tests can also be improved with a better strategy to noise in the simulation. However, in spite of these slight problems, it seems the broad aim of evolving controllers with a dynamic approach to colour perception has been met, and the agents are able to detect contrast in a number of scenes where this would otherwise be impossible.

This work has been undertaken as a theoretical proof-of-concept: to show that the desired road following and dynamic colour perception behaviours can be produced through artificial evolution of neural network controlled robots. The transferral of such a system onto real robotics hardware has not been broached. We are aware that there are a number of issues which may affect the ability of this evolved controller to successfully cross the "reality gap". Future work will concentrate on this challenge.

## Abstract

Evolutionary algorithms can adapt the behavior of individuals to maximize the fitness of cooperative multi-agent teams. We use a genetic algorithm (GA) to optimize behavior in a team of simulated robots that mimic foraging ants, then transfer the evolved behaviors into physical iAnt robots. We introduce positional and resource detection error models into our simulation to characterize the empirically-measured sensor error in our physical robots. Physical and simulated robots that live in a world with error and use parameters adapted specifically for an error-prone world perform better than robots in the same error-prone world using parameters adapted for an error-free world. Additionally, teams of robots in error-adapted simulations collect resources at the same rate as the physical robots. Our approach extends state-of-the-art biologically-inspired robotics, evolving high-level behaviors that are robust to sensor error and meaningful for phenotypic analysis. This work demonstrates the utility of employing evolutionary methods to optimize the performance of distributed robot teams in unknown environments.

## Introduction

Multi-agent simulations have been used to evolve behaviors which are then transferred into physical robots (Nelson et al., 2004; Singh and Parhi, 2011). Simulations rapidly generate multiple viable solutions, allowing researchers to test many possible scenarios and make informed decisions about which physical experiments to run. Such simulations should focus on physical fidelity by replicating the environment, hardware constraints, and sensor error of the real robots (Brooks, 1992).

A particularly challenging class of problems for multi-robot systems is central-place foraging (Matarić, 1994; Panait and Luke, 2004). For this task, robots are programmed to search an area for resources and aggregate these resources at a central location. Foraging is considered a canonical task for distributed robotics: foraging can be instantiated into a number of real-world applications such as hazardous waste clean-up (Parker, 1998), land mine detection and removal (Gage, 1995; Kong et al., 2006), search and rescue (Kitano et al., 1999), and extraplanetary exploration (Curtis et al., 2003; Tunstet et al., 2008). For applications

where the physical environment may vary over time and the distribution of resources is most likely unknown, evolutionary approaches allow robot teams to adapt their behavior to each particular scenario.

Our robots use a central-place foraging algorithm (CPFA) based on the foraging behavior of ants (Hecker et al., 2012; Hecker and Moses, 2013). The CPFA is parameterized by a GA in a multi-agent simulation which emulates the physical robot experiments. Our simulation evolves parameters in a parsimonious model of biological ant behavior, and our iAnt robots use these parameters to forage for resources in an experimental area. We investigate the effects of sensor error on physical and simulated robot performance. We demonstrate the utility of this approach by measuring the number of resources that robots collect using parameters adapted and not adapted to error.

## Previous Work

We conducted manipulative field studies on three species of *Pogonomyrmex* desert seed-harvester ants (Flanagan et al., 2012). Colonies were baited with dyed seeds distributed in a variety of pile sizes around each ant nest. We calculated foraging rates for each distribution and found that ants collected seeds faster when seeds were more clustered. Computer simulations used genetic algorithms to find individual ant behavioral parameters that maximized the seed collection rate of the colony. Simulated ants foraging with those parameters mimicked the increase of seed collection rate with the amount of clustering in the seed distribution when ant agents were able to remember and communicate seed locations (Paz Flanagan et al., 2011).

We also observed how individual parameters and overall fitness change with different distributions of resources and different numbers of simulated agents performing a central-place foraging task (Letendre and Moses, 2013). Parameters evolved for specific types of resource distributions were swapped and then fitness was measured for the new distribution; for example, parameters optimized for a clustered distribution were tested on random distributions of resources. Simulated agents incurred as much as a 50% decrease in fit-

ness when using parameters on a distribution different from the one for which they were optimized.

We then modified our multi-agent central-place foraging simulation to model the physical environment and hardware constraints of our iAnt robot platform (Hecker et al., 2012). We adapted our existing GA to evolve parameters for our iAnt robots. The evolved parameters were then transferred into the physical robots. Simulated teams collected three to four times as many resources as the real robot teams. We hypothesized that this discrepancy resulted from a *reality gap* between the error-free simulated world and the sensor error experienced by the physical robots.

Most recently, we incorporated a probabilistic error model into our multi-agent iAnt simulator in a workshop paper (Hecker and Moses, 2013). In this preliminary study, we added varying amounts of noise to agents' physical positions and their ability to detect resources, and analyzed the response of the genetic algorithm by observing individual behavioral parameters. We saw that increased positional error reduced resource collection, and induced the GA to select for a lower likelihood of returning to locations where resources were previously found. Increased detection error also reduced resource collection, as well as influencing the GA to select behaviors that searched local areas more thoroughly when only a few resources were detected. These behaviors indicated that the GA was able to evolve parameters appropriate to the sensor error used in the simulation.

We build on this prior work by *a)* simplifying the CPFA which improves performance and makes it easier to interpret why parameters are evolved to different values in different experiments; *b)* updating the iAnt simulator to more accurately reflect physical reality; *c)* testing the CPFA on new resource distributions; and *d)* implementing error-adapted parameters in experiments in physical robots.

## Background

Research in evolutionary robotics (ER) primarily focuses on using evolutionary methods to develop controllers for autonomous robots. Controllers can be evolved in simulation and subsequently transferred into physical robots (Nelson et al., 2004; Singh and Parhi, 2011), or evolved directly in real robots through embodied evolution (Watson et al., 2002). Following principles outlined by Brooks (1991), work in ER has focused on bridging the reality gap between simulated and real robots to improve the performance of evolved controllers in the physical world (Jakobi et al., 1995). Neural networks have been used in combination with evolutionary methods to evolve controllers for simulated robot agents with random sensor noise; controllers were subsequently transferred to real robots with varying degrees of success (Nolfi et al., 1993; Miglino et al., 1995; Jakobi, 1997).

State-of-the-art robotic simulators such as Stage (Vaughan, 2008) and ARGoS (Pinciroli et al., 2011) can

Figure 1: Our approach leverages studies on biological ants, multi-agent simulations guided by genetic algorithms, and our physical iAnt robot platform.

be used to model large robot teams with realistic, complex physical kinematics, but they do not incorporate any learning or evolutionary methods that allow simulated agents to adapt to unknown environments. Neither simulator includes sensor noise in its standard implementation, however Pinciroli et al. (2012) recently modified ARGoS to incorporate an actuator noise model, generating performance matching results from positional error observed in real robots.

Previous work on multi-robot group foraging tasks used reinforcement learning to train robots on higher-level behaviors, rather than lower-level motor controllers or basic directional responses (Matarić, 1997a,b). Robots learned when to switch between behaviors in a fixed repertoire set through positive and negative reinforcement related to their foraging success. We follow this high-level learning approach in the design of our CPFA.

Our approach (see Figure 1) differs from previous approaches in that we do not attempt to evolve basic primitive behaviors from the ground up. Instead, we model existing biological ant behaviors that have evolved naturally over millions of years. We use a genetic algorithm to parameterize these behaviors in our simulated agents, then we transfer those behaviors into physical robots. Evolved parameters control the sensitivity threshold for triggering behaviors, the likelihood of transitioning from one behavior to another, and the length of time each behavior should last.

We extend the state of the art in evolutionary and biologically-inspired robotics by *i)* evolving high-level behaviors that are *ii)* robust to real-world sensor error and *iii)* meaningful for phenotype-level analysis.

## Methods

We present our simulated model of ant behavior, detailed pseudocode and diagrams explaining our simplified CPFA,

probabilistic models of physical sensor error in the iAnt robot platform and implemented in our multi-agent system, and the design of our simulated and physical experiments.

### Ant Behavior Model

*Pogonomyrmex* seed-harvester ants follow a central-place foraging strategy to aggregate food at their colony's single nest. These foragers typically leave their nest, travel in a relatively straight line to some location on their territory, and then switch to a correlated random walk to search for seeds. A foraging ant who has located a seed brings it directly back to the nest. Foragers often return to a location where they have previously found a seed in a process called site fidelity (Moses, 2005; Beverly et al., 2009; Flanagan et al., 2012). Our recent work indicates that combining site fidelity with occasional laying of pheromone trails to dense piles of food may be an effective component of these ants' foraging strategies (Paz Flanagan et al., 2011; Letendre and Moses, 2013).

We incorporate key behaviors observed in our previous field studies on desert seed-harvester ants (Flanagan et al., 2012) into our multi-agent simulation and physical iAnt robots. We model probabilistic actions and state transitions using eight evolvable parameters, detailed in Table 1. These are simplifications of our earlier CPFA algorithm (Hecker et al., 2012). Modifications have been made since our most recent work in an effort to increase parsimony (Hecker and Moses, 2013), such as removing the parameter for probabilistically abandoning a pheromone waypoint:

- **State transitions:** Robots switch between two behaviors:
  - **Traveling:** In the absence of information, a robot at the nest will select a random direction and begin traveling. At each step of traveling, robots have a probability  $p_s$  of transitioning to search behavior.
  - **Searching:** At each step of searching, robots who have not found a resource have a probability  $p_t$  of returning to the nest.
- **Correlated random walk:** Robots explore regions using a random walk with a fixed step size and a direction  $\theta_t \sim \mathcal{N}(\theta_{t-1}, \sigma)$  at time  $t$ . The standard deviation  $\sigma$  determines how correlated the direction of the next step is with the direction of the previous step.  $\sigma$  depends on whether an agent has prior information through the use of site fidelity or pheromones:
  - **Uninformed search:** If an agent has not used site fidelity or pheromones, then  $\sigma = \omega$ .
  - **Informed search:** If an agent has arrived at a site by using site fidelity or pheromones, then  $\sigma = \omega + (4\pi - \omega) * e^{-\lambda_{id} * t}$ , where  $\sigma$  decays to  $\omega$  as time  $t$  increases.
- **Information:** Previous ant studies have demonstrated the ability of ants to count event frequencies in estimating

| Parameter      | Description                   | Initialization Function |
|----------------|-------------------------------|-------------------------|
| $p_t$          | Probability of traveling      | $\mathcal{U}(0, 1)$     |
| $p_s$          | Probability of searching      | $\mathcal{U}(0, 1)$     |
| $\omega$       | Uninformed search correlation | $\mathcal{U}(0, 4\pi)$  |
| $\lambda_{id}$ | Informed search decay         | $exp(5)$                |
| $\lambda_{lp}$ | Rate of laying pheromone      | $exp(1)$                |
| $\lambda_{fp}$ | Rate of following pheromone   | $exp(1)$                |
| $\lambda_{sf}$ | Rate of site fidelity         | $exp(1)$                |
| $\lambda_{pd}$ | Rate of pheromone decay       | $exp(10)$               |

Table 1: Set of 8 parameters evolved in simulation guided by genetic algorithms. At the start of a simulated run, parameters in each colony are initialized using randomly sampled values from their associated initialization function. The first 3 parameters are initially sampled from a uniform distribution, and the last 5 from exponential distributions within the stated bounds.

nest size (Mallon and Franks, 2000), travel distance (Witlinger et al., 2006), and encounter rates with other ants (Prabhakar et al., 2012). In our simulation, when an agent finds a resource, it stores a count  $c$  of additional resources in the 8-cell neighborhood of the found resource. This count  $c$  represents an estimate of the density of resources in the local region, and the agent uses  $c$  to decide when to use site fidelity, lay a pheromone waypoint, or follow a pheromone waypoint:

- **Site fidelity:** A robot returns to a previously found resource location if  $F_{sf}(c) > \mathcal{U}(0, 1)$ , where  $F_{sf}(x) = 1 - e^{-\lambda_{sf} * (x+1)}$ .
- **Laying pheromone:** A robot creates a pheromone waypoint for a previously found resource location if  $F_{lp}(c) > \mathcal{U}(0, 1)$ , where  $F_{lp}(x) = 1 - e^{-\lambda_{lp} * (x+1)}$ . New pheromone trails are initialized with a value of 1.
- **Following pheromone:** Upon returning to the nest, a robot follows a pheromone waypoint to a previously found resource location if  $F_{fp}(c) > \mathcal{U}(0, 1)$ , where  $F_{fp}(x) = 1 - e^{-\lambda_{fp} * (9-x)}$ . Waypoints are selected with probability proportional to their pheromone value.
- **Pheromone decay:** Pheromone waypoints decay exponentially over time  $t$  as  $e^{-\lambda_{pd} * t}$ . Waypoints are removed from the simulation once their value drops below a threshold of 0.001.

Four parameters that are of interest in our analysis are the informed search decay rate ( $\lambda_{id}$ ), the rate of using site fidelity ( $\lambda_{sf}$ ), the rate of laying pheromone ( $\lambda_{lp}$ ), and the rate of following pheromone ( $\lambda_{fp}$ ). Lower values of informed search decay ( $\lambda_{id}$ ) cause the robots to use a less correlated

random walk, and thus a more random and thorough local search, for a longer period of time when they have information pertaining to a high density of resources at a particular location.

In both simulated and physical robots, we simulate pheromone trail use by maintaining a list of waypoints. Pheromone strength of each waypoint evaporates over time ( $\lambda_{pd}$ ). Physical marking is not possible with real robots, and therefore our simulated agents follow the same protocol.

### Search Algorithm

CPFA pseudocode is shown in Algorithm 1. Note that probabilities of using site fidelity ( $F_{sf}(c)$ ), laying pheromone ( $F_{lp}(c)$ ), and following pheromone ( $F_{fp}(c)$ ) are generated using the equations discussed in the previous subsection. Figure 2(a) shows a state diagram of the algorithm, and Figure 2(b) illustrates an example of one possible cycle through the search behavior loop. An iAnt robot is shown in Figure 2(c).

### Physical Sensor Error

Two sensing components are precise in simulation but error-prone in our physical iAnt robot platform: positional measurement and resource detection. Our physical robots use

a combination of ultrasonic distance, magnetic compass headings, time-based odometry, and an on-board forward-facing camera to estimate their position within the experimental area. Resource detection is accomplished using a downward-facing camera to read barcode-style QR tags.

We measured positional error in five physical robots while localizing to measure the absolute position of a found resource, and while traveling to a location informed by site fidelity or pheromones. We replicated each test 20 times per robot; means and standard deviations for both types of positional error were calculated using 120 samples each. For robots localizing at a true position of (0 cm, 0 cm), we observed a measured position of  $(-18 \pm 79 \text{ cm}, -15 \pm 47 \text{ cm})$ , whereas robots traveling to a true position of (0 cm, 0 cm) had a measured position of  $(1.6 \pm 45 \text{ cm}, 64 \pm 110 \text{ cm})$ .

Positional error is modeled by perturbing the physical position of an agent from  $(x, y)$  to  $(x', y')$ , such that  $x' \sim \mathcal{N}(x + \hat{x}, \sigma_x)$  and  $y' \sim \mathcal{N}(y + \hat{y}, \sigma_y)$ . That is,  $(x', y')$  is sampled from a normal distribution with mean equal to the true position  $(x, y)$  offset by  $(\hat{x}, \hat{y})$ , and standard deviation  $(\sigma_x, \sigma_y)$ . We impose this positional perturbation twice: once when a robot finds a resource, and again when a robot leaves the nest using site fidelity or following a pheromone waypoint to a known location.

We observed resource detection error for physical robots searching for resources, and for robots searching for neighboring resources. Resource-searching robots attempt to physically align with a QR tag, using small left and right rotations and forward and backward movements to center the tag in their down-facing camera. Robots searching for neighboring resources do not use this alignment strategy, but instead simply rotate  $360^\circ$ , scanning for a tag every  $10^\circ$  with their down-facing camera. We replicated each test 20 times for three different robots; means for both types of resource detection error were calculated using 60 samples each. We observed that resource-searching robots detected 55% of tags and neighbor-searching robots detected 43% of tags. Resource detection is modeled as a fixed probability  $d_r = 0.55$  for resource-searching robots, and  $d_n = 0.43$  for neighbor-searching robots.

### Experimental Design

Each experimental physical trial on a 100 m<sup>2</sup> concrete surface runs for 30 minutes. An illuminated beacon marks the center ‘nest’ to which the robots return once they have located a resource. This center point is used for localization and error correction by the robots’ ultrasonic sensors, magnetic compass, and front-facing camera. All robots involved in a trial are initially placed near the beacon. Robots are programmed to stay within a 5 m ‘virtual fence’ of the beacon. In every experiment, 256 QR tags are arranged in 4 randomly placed clusters of 64 tags each.

Robot locations are continually transmitted over one-way WiFi communication to a central server and logged for later

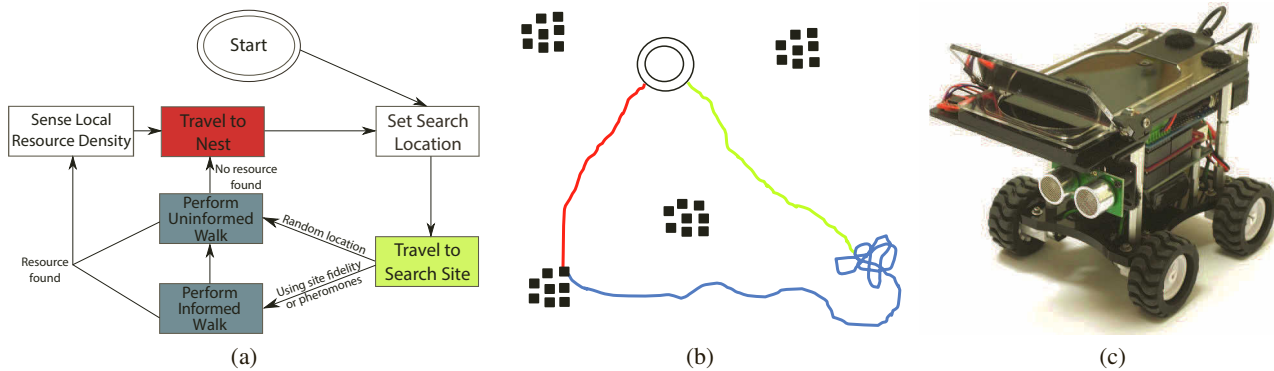

Figure 2: (a) State diagram describing the flow of behavior for individual robots during an experiment, (b) an example of a single cycle through this search behavior loop, and (c) an iAnt robot with Velcro for attaching reflective markers (motion capture was used for a previous experiment (Bezzo et al., 2013), but not for any of the observations in this paper). The robot begins its search at a central nest site (double circle) and **sets a search location**. The robot then **travels to the search site** (yellow line). Upon reaching the search location, the robot **searches for resources** (blue line) until a resource (black squares) is found. After sensing the local resource density, the robot **travels to the nest** (red line).

analysis. When a tag is found, its unique identification number is transmitted back to the server, providing us with a detailed record of tag discovery. Tags can only be read once, simulating seed retrieval. The central server also acts as a coordinator for pheromone waypoints using two-way communication. As each robot returns to the nest, the server selects a location from the list (if available) and transmits it to the robot.

Simulated teams of five robots search for resources on a 125 x 125 cellular grid. The system architecture replicates the physical dimensions of our real robots, their speed while traveling and searching, and the area over which they can detect resources. The spatial dimensions of the grid reflect the distribution of resources over a 100 m<sup>2</sup> physical area, and agents search for a simulated half hour. 256 identical resources are placed on the grid (each resource occupies a single grid cell) in one of three distributions: random (each resource placed at a random location), clustered (4 randomly placed clusters of 64 resources each), or power law (1 large cluster of 64, 4 medium clusters of 16, 16 small clusters of 4, and 64 randomly scattered). Each individual pile is placed at a new random, non-overlapping location for each fitness evaluation in an effort to avoid bias or convergence to a specific resource layout.

A population of 200 teams is evolved for 100 generations using recombination and mutation. Each team's parameter set is randomly initialized using uniform independent samples from each parameter's initialization function (see Table 1, column 3); agents within a team use identical parameters throughout the simulation. Each team forages for resources on its own grid, but the grids are identical. During each generation, all 200 teams undergo eight evaluations with different random placements of tag clusters; fitness is evaluated

as the sum total of resources collected by each team in the eight runs of a generation. Two individual teams are chosen through tournament selection and recombined through independent assortment: each parameter has a 10% chance of being selected from the second individual, otherwise it is selected from the first individual. Once selected, each parameter has a 10% chance of mutation.

We additionally conduct a series of *parameter swapping* experiments, in which we transfer a parameter set evolved in a simulated error-free world to a world with error. We compare the performance for parameters adapted to error to results using the original parameters not adapted to error. For these experiments, we average the resources collected across multiple replicates. In this way, we can determine the importance of including error in our model by testing whether it has a significant effect on the evolved behavior of the physical and simulated robot teams.

## Results

We present results for teams of five physical and simulated robots searching for resources in worlds with and without sensor error. Unless otherwise noted, results for each experimental treatment are averaged over five physical replicates and ten simulated replicates. Error bars indicate one standard deviation of the mean.

Figure 3 shows parameter values influencing robots' use of information ( $\lambda_{sf}$ ,  $\lambda_{lp}$ , and  $\lambda_{fp}$ ), as well as the informed walk decay rate ( $\lambda_{id}$ ) for random, clustered, and power law distributed resources. We observe similar values for all four parameters for clustered and power law distributions: robots evolve a high rate of following pheromones and a low rate of using site fidelity. Robots foraging on random distributions evolve both a high rate of following pheromones and

Figure 3: Parameter values for rates of site fidelity ( $\lambda_{sf}$ ), laying pheromone ( $\lambda_{lp}$ ), following pheromone ( $\lambda_{fp}$ ), and informed random walk decay ( $\lambda_{id}$ ) for random, clustered, and power law distributed resources.

a high rate of using site fidelity, but the effective probability of using either behavior are actually low because of the dependencies between them (see Algorithm 1).

Figure 4 shows fitness curves and parameter values adapted for simulated foraging for resources on a clustered distribution. Figure 4(a) plots best and mean fitness over 100 generations for worlds with and without positional and resource detection error modeled on our physical iAnt robots.

We observe fitness stabilizing after approximately 20 generations. Simulations with error converge to a fitness level approximately 33% of the fitness achieved in simulations without error. Figure 4(b) shows parameter values influencing robots' use of information ( $\lambda_{sf}$ ,  $\lambda_{lp}$ , and  $\lambda_{fp}$ ), as well as the informed walk decay rate ( $\lambda_{id}$ ). Robots foraging in an error-free world evolve a high rate of following pheromones (1.2) and a low rate of using site fidelity (0.013), whereas robots in a world with error evolve a high rate of site fidelity (1.7) and a low rate of following pheromones (0.0071). Additionally, in worlds with error, robots are 2.4 times more likely to lay pheromones, and their informed random walk decays 1.8 times faster than in an error-free world.

We analyze the performance of physical and simulated robots foraging in a world with error using parameters adapted specifically for the error-prone world. We compare the results to robots in a world with error using parameters adapted for an error-free world. Figure 5 shows the effects of parameter swapping on resource collection for physical and simulated robots (simulated results are averaged over 100 replicates). We observe an 80% improvement using the error-adapted parameters in physical robot teams, and a 16% improvement in simulated robot teams. We were able to distinguish a significant effect of parameter swapping in physical robots ( $t(8) = 5.1, p < 0.001$ ) and in simulation ( $t(198) = 17, p < 0.001$ ). Although simulated robots collect more resources than physical robots when using non-error-adapted parameters, we find that physical and simulated robots using error-adapted parameters are not significantly different ( $t(103) = 0.16, p = 0.87$ ).

Figure 4: Results for simulated foraging on a clustered resource distribution with and without error. (a) Best and mean fitness curves. (b) Parameter values for rates of site fidelity ( $\lambda_{sf}$ ), laying pheromone ( $\lambda_{lp}$ ), following pheromone ( $\lambda_{fp}$ ), and informed random walk decay ( $\lambda_{id}$ ).

Figure 5: Results for physical and simulated robots foraging in a world with error using parameters adapted for a world with error, and parameters adapted for an error-free world. 80% more resources are collected using error-adapted parameters in physical robot teams, and 16% more are collected in simulated teams. Robots collected significantly more resources in both cases. Physical and simulated robots using error-adapted parameters are not significantly different.

## Discussion

Teams of physical and simulated robots used a central-place foraging algorithm (CPFA) to search for resources with and without sensor error. A genetic algorithm (GA) was used to evolve parameter sets which corresponded to robot team behaviors inspired by seed-harvester ants. We considered two types of error, positional error and resource detection error, and we explored the effects of error on overall resource collection and on individual evolved parameters. Error-adapted parameters improved performance of physical and simulated robots in worlds with error. We observed that teams of robots in error-adapted simulations collected resources at the same rate as physical robots.

Both positional and detection errors have the potential to confound a robot's ability to properly use information to exploit resources clustered via site fidelity or pheromones. Large positional errors in the estimation of resource locations can cause robots to perform informed random walks in regions without resources, thereby wasting time in detailed searches of the wrong areas. Errors in detecting resources can cause robots to underestimate the numbers of resources in a local area, so that robots fail to take advantage of memory or communication to return or recruit other agents to resource-rich locations.

Evolutionary algorithms have the potential to mitigate sensing errors by selecting for parameters which perform optimally given imperfect conditions. For example, robots

experiencing errors in resource detection benefit from a lower threshold of resource density detection for triggering creation of a pheromone waypoint. Robots with positional errors perform better with a faster decaying informed random walk, so that they quickly abandon detailed searches when there is a high probability that resources are not in remembered or communicated locations.

Parameter values for simulated robots foraging on random, clustered, and power law distributed resources (Fig. 3) illustrate the GA's ability to evolve sets of behaviors for each distribution. Parameters for clustered and power law distributions are similar, demonstrating the ability of the GA to focus on exploiting clumped resources when available. The lack of clustering in the random distribution induces the GA to effectively disable site fidelity and pheromone following behaviors, thus causing the adapted robot teams to concentrate on random exploration.

Fitness curves for simulations with and without error (Fig. 4(a)) demonstrate the ability of the GA to reliably converge. Parameter values (Fig. 4(b)) demonstrate the ability of the GA to evolve distinct sets of behaviors for an error-free world compared to a world with error.

Results for parameters swapped from error-free worlds into worlds with error (Fig. 5) show that parameters adapted for imperfect worlds outperformed parameters adapted for perfect worlds. Teams of physical and simulated robots collected similar numbers of resources, particularly when using parameters adapted for error. Thus, evolutionary methods effectively adapt robot behavior to sensor error. These results also mirror observations from our previous work in which genetic algorithms were used to evolve optimal parameter sets for specific types of resource distributions.

The work presented here motivates estimation of real robot error, evolution of parameters to fit with that error, and programming of those evolved parameters into real robots. In future work, we will conduct additional physical and simulated robot experiments using different numbers and distributions of resources, arena sizes, numbers of robots, and modes of communication to test whether simulations and physical experiments continue to correspond as closely as we have observed here.

## Abstract

Genetic recombination is commonly used in evolutionary algorithms and yet its benefits are an open question in evolutionary biology. We investigate when recombination is actually beneficial in the evolutionary adaptation of swarm robot behaviour in dynamic environments. In this scenario, artificial evolution has to deal with challenges that are similar to natural evolution: it must run online, distributed and evolve the genome structure. These requirements could diminish the benefit of recombination due to disruptive crossover. Using neural networks as robot controllers, we reduce this disruptiveness with an adaptive mate choice that evolves the probability of recombination and the genetic similarity of mates. In two experiments with a multi-agent simulation, we compare the adaptive performance of this approach with random recombination and pure mutation. Whereas both recombination treatments naturally outperform at low mutation rates, pure mutation achieves its best performance with high rates, where it also outperforms random recombination. The adaptive mate choice, however, achieves the same performance as pure mutation at high rates and outperforms when the network size is increased. We also found that treatments with recombination evolved smaller neural networks with fewer links.

## Introduction

It is a major challenge to give artificial, autonomous systems adaptive and problem solving capabilities. One approach to this problem attempts to mimic the impressive results of natural evolution by emulating its mechanisms like mutation, recombination and selection in so-called evolutionary algorithms (Eiben and Smith, 2003). The prevalence of recombination in evolutionary algorithms is interesting, given that it is not essential for an evolutionary process and because it is an ongoing discussion in evolutionary biology why sex and recombination is beneficial (Rice, 2002). Sex is considered costly because asexuals can potentially reproduce twice as fast (Maynard Smith, 1978). But sex is predominant in nature, a fact that numerous theories attempt to explain by attributing benefits to sexuality and recombination that compensate for those costs (West et al., 1999). One prominent argument is that sex accelerates adaptation to changing environments (Bell, 1982). In evolutionary algorithms however,

recombination is not considered costly because there is no actual reproduction and benefits have been shown in many cases (Eiben and Bäck, 1997; Doerr et al., 2008).

In this work, we investigate recombination in the case of evolution of swarm robot behaviour in dynamic environments. This case has special requirements for the evolutionary algorithm that make it more similar to natural evolution, and we wonder if recombination still exhibits clear benefits. In swarm robotics, many small robots are deployed with limited individual capabilities but the swarm can have emergent capabilities through cooperation (Sahin, 2005). Due to the difficulty of developing cooperative behaviour for swarm robots, evolution is often employed for this purpose (Haasdijk et al., 2010; Bredeche et al., 2010). One major challenge in swarm robotics is to make the swarm fully autonomous and adaptive so it can operate independently in the dynamic, real world — which is similar to what natural organisms do.

The special requirements of this challenge complicate the application of conventional evolutionary approaches, for example Evolution Strategies (Beyer and Schwefel, 2002). First, swarm robotics avoids using a central supervising instance because the robots should operate autonomously with only local information. Many evolutionary algorithms are centralized and not capable for such distributed operation. Second, to be able to deal with a-priori unknown and dynamic environments, constant adaptation is required which necessitates an online evolutionary algorithm (Agogino et al., 2000). Online evolution optimizes a system in parallel while it is deployed in its task. Every candidate evaluation is done in the local, variable conditions and affects total system performance whereas offline evolution can evaluate under repeated, constant conditions and deploy only the best solutions. And last, a large flexibility in evolvable behaviours is needed to deal with unknown environments. We use here neural networks, which are a well established approach for evolving robot behaviour (Floreano and Mondada, 1994). It has been shown that evolving the structure of the neural networks by adding and removing neurons and links increases the flexibility and is advantageous (Stanley and Miikkulainen, 2002). However, structural evolution

of neural networks complicates their recombination and can lead to disruptive macro mutations unless network structures are correctly matched, for example in NEAT (Stanley and Miikkulainen, 2002).

There exist evolutionary algorithms that address each of those requirements individually but not simultaneously. We have recently developed an approach to fill this gap for distributed online evolution with structural evolution of neural networks (Schwarzer et al., 2011). With this approach, we investigate here when recombination is beneficial in a simulation experiment with four robots in a foraging task. This is a very low number for a swarm, but it tests the effectiveness of the evolutionary algorithm even with limited resources. The approach can be scaled up and is applicable to real swarm robots because information is exchanged only locally. Our expectation is that recombination increases the speed of adaptation and that in a limited time, an unfit population increases its performance faster than when only mutation is used.

The mutation rate is a crucial parameter of this comparison because it is known that increasing the mutation rate increases the speed of adaptation until it reaches a point where performance is reduced, called the error threshold (Eigen, 1971; Ochoa and Harvey, 1999). We also include different neural network sizes in the comparison because it has been shown that longer genomes can reduce the error threshold (Ochoa, 2006).

## Material and Methods

The experimental setup is an extension of our previously published study (Schwarzer et al., 2011). Compared to the earlier work, the genome structure and evolutionary algorithm have been expanded to improve the performance of recombination.

### Genome and Neural Network

The genome encodes a recurrent neural network with a variable number of hidden neurons. Any connection between hidden neurons is possible. The employed neuron model uses the weighted sum of inputs with bias and sigmoid activation function.

In Figure 1, an overview of the genome structure is shown which differs from our earlier approach. The genome is now diploid with two homologous chromosomes. Each chromosome is an array of gene sites is used, each gene site can be free or occupied with a gene. This arrangement makes it possible to mutate the chromosome by relocating genes to free spots without shifting the absolute positions of other genes. In this way, crossover is simplified because the majority of genes in related chromosomes always line up at the same position. There are two different gene types: node gene and link gene. A node gene contains a node ID and a bias value for the activation function; it produces a node

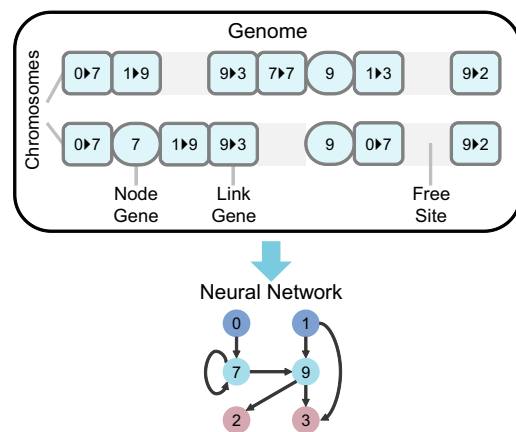

Figure 1: The genome has two chromosomes. A chromosome is an array of gene sites which can be occupied or empty. Genes come in two types, node genes and link genes. A node gene creates one node in the neural network, a link gene creates one link.

with the respective ID and parameters. A link gene contains two node IDs and a link weight; if there are node genes for both IDs, a neural link is created between them with the given weight. When new nodes are generated during mutation, they are assigned a random identifier. The identifier is used to recognize if two genes on the same gene site share a common ancestry.

A value can be calculated between two chromosomes that describes the genetic similarity  $s$  from 0 (completely different) to 1 (identical) in a similar way to the Sørensen Index (Sørensen, 1948). It is computed by comparing each homologous gene site, counting similar sites  $c$  and number of sites of both genomes ( $n_a$ ,  $n_b$ ) according to the following formula:

$$s = \frac{2 \cdot c}{n_a + n_b}$$

Genes are similar when they use the same node IDs. For the similarity between two genomes, the chromosomes are paired and the pairwise chromosome similarity values are averaged.

The genes of both chromosomes are used to create the neural network. Thus, it occurs regularly that there are multiple genes encoding the same structural element. This is normally the case for genes on homologous sites but also possible with genes across different sites due to relocation and recombination. These genes can have different parameters (weights, bias) for the same structure similar to different alleles in biology. In such cases, a dominance value is computed for the duplicate genes based on their parameter values. Dominant and recessive parameter values are evenly and finely distributed across the range of possible values. Only the allele with the highest dominance value is used and if multiple, different allele have the same dominance, their

parameters are averaged.

Outside of this chromosome structure, the genome contains three evolvable parameters. One mutation factor that is multiplied to the standard deviation of parameter mutation operations and to the probability of structural mutations. A mutation factor with a value of 1 leads to the default, unaltered mutation rate; values larger than 1 increase and smaller than 1 decrease it. The two other parameters are used for the adaptive mating mechanism explained in more detail in the description of the evolutionary algorithm.

Mutation of the genome is done on a per-gene-basis. Every gene is subjected to parameter mutation where weight and bias are mutated using a normal distribution with  $\sigma = 0.01$ . With a probability of 0.05, a gene undergoes structural mutation: a node gene changes its node ID to a new random ID and a link gene changes its source or destination ID to a different one that is already present on the genome. Furthermore, the gene may be completely removed ( $p=0.01$ ), duplicated with the copy being moved to a random position on the chromosome ( $p=0.01$ ) or relocated to a random, free site on the chromosome ( $p=0.02$ ).

An offspring genome is created similar to meiosis. First, a mutated copy of the whole genome is created for each parent. Then the chromosomes in each copy are crossed over with a probability of 0.02 per gene site. One resulting chromosome is picked from each parent and subsequently fused to form a diploid offspring genome.

## Evolutionary Algorithm

One instance of the evolutionary algorithm runs on each simulated robot and maintains an island population of ten genomes that serve as parental genome pool. In one cycle of online evolution, one offspring genome is generated from this genome pool and used to create a neural network. The neural network controls the robot for 2,500 simulation ticks (about 50 seconds in real time) during which it is evaluated based on the expressed behaviour. At the end of this time, the offspring genome may survive and replace one member of the island population, or it may be discarded, depending on its evaluation. Genomes also migrate between island populations independently of the evaluation cycle. When two robots are in close proximity of each other, one robot transmits and removes one random genome from its population; the recipient responds by sending a random genome back. This exchange occurs at most once every 10,000 ticks per robot. There are alternative approaches for this migration process which are possibly more effective, for example by only transmitting the best genome, but the given approach is sufficient for the purpose of this work in creating one virtual large population. The operation of this evolutionary algorithm is illustrated in Figure 2.

In order to create an offspring, one parent genome of the island population is selected randomly. We call this genome female here, but note that the genomes are equivalent to

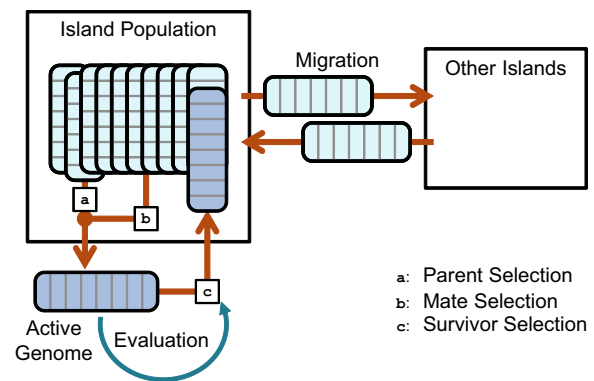

Figure 2: Operation of the distributed online evolutionary algorithm (Schwarzer et al., 2011). An island population is an instance of the distributed algorithm that runs on each robot. It maintains a constant number of genomes that serve as parental genome pool from which offspring genomes are created for evaluation. Genomes are occasionally exchanged between island populations.

hermaphrodites; each genome can have offspring with any other genome within the island population. The female can select a mate for recombination, depending on the employed mate selection strategy. If mate selection decides to not pick a mate, a mutated copy of the female is generated as offspring, which is always the outcome in the treatment without recombination. With random mating, mate selection picks a random genome from the island population (excluding itself). The adaptive mate selection strategy uses evolvable parameters of the female to influence the selection of the mate. First, the genetic similarity between the female and all other genomes of the local population is calculated. These similarity values are evaluated with a Gaussian function, with  $\mu$  and  $\sigma$  given by the female genome, to result in a value of “attractiveness” for each mate between 0 and 1. In other words, genomes have an evolvable value for the ideal genetic similarity of mates, and they can also evolve how much they are willing to deviate from this ideal. One mate is picked from the candidates with a random roulette selection, using the attractiveness as weights so candidates whose genetic similarity is closer to the ideal value have a larger likelihood of being chosen. However, it is also possible that no mate is picked when the sum of attractiveness of all candidates is less than 1. This can occur on purpose when the genome evolves, for example, a narrow range of acceptable values; it has then effectively reduced the probability of recombination.

In the survivor selection, which is identical in all three treatments, the freshly evaluated candidate genome is compared to the genomes in the island population and a special metric, which we call “fitness score” is used. The fitness score is the average of the last six offspring evaluations of a genome. A genome in the island population that did not

Figure 3: Screenshot of the experimental arena. The four simulated robots are shown with the approximate coverage of their visual sensors. Ten power stations are present that show their state by their colour: blinking red represents “charged”, black “depleted” or “charging”.

have six offspring yet, uses its own evaluation to seed this moving average. The candidate genome must have an evaluation greater than the worst fitness score in the population to survive and replace this worst genome. This mechanism makes the evolutionary algorithm tolerant to changes in the environment. A genome that once evaluated well will produce unfit offspring in a different environment, its fitness score drops as a result of low offspring evaluations and it can be more easily surpassed.

### Scenario and Simulation Environment

We use a foraging scenario that was designed to be practical and realizable in existing hardware. It requires search, identification and harvesting of power sources; an essential task of an autonomous swarm. The particular challenge for the neural network evolution is the processing of visual, colour information to distinguish resources from surroundings.

The experiment is done in the same 2D multi-agent simulation of our previous study (Schwarzer et al., 2011) and uses a similar scenario: four robots are in an arena with ten power stations that can be harvested by being next to them (see Fig. 3 for a visualisation of the arena). The stations charge only slowly and the best strategy is to continuously search the arena for nondepleted power stations.

The robots are modelled after a small, agile swarm robot like the e-puck (Mondada et al., 2009) or Wanda (Kettler et al., 2010) with a differential drive, distance sensors and a visual sensor that could be derived from an on-board camera. This visual sensor provides the robot with an RGB colour signal from three sectors, each  $20^\circ$  wide, covering together an area of  $60^\circ$  in front of the robot. One proximity sensors is also present in each of the three sectors.

All objects in the arena have a colour appearance. In order

| Factor                            | Values                 |
|-----------------------------------|------------------------|
| Recombination                     | None, Random, Adaptive |
| Initial Mutation Factor           | 0.031, 0.125, 1, 8, 32 |
| Adaptive Mutation                 | Disabled, Enabled      |
| Initial Neuron Count              | 0, 6, 14               |
| Colour Cycle Time (million ticks) | 0.1, 0.25, 0.5, 1, 2   |

Table 1: Factors of the experimental setup. Colour cycle time is only used in the colour cycle experiment.

to present a challenge that requires more complicated neural processing, the power stations are blinking by alternating their appearance between black and an active colour every five ticks. Depleted power stations do not blink and stay black until they have recharged some energy. A changing environment is simulated by changing the active colour of all power stations.

The current evaluation of a robot is increased every time it is next to an undepleted power station; at the same time, the current charge of that station is decreased. The time needed to fully drain a station is variable: the maximum time is 1,000 ticks, less time is needed when the robot decelerates. In this way, a robot can harvest from multiple stations within its 2,500 ticks of evaluation time, and the fastest way to gain reward is to come to a full halt next to a power station that is fully charged. Since a rarely visited power station is likely fully charged, exploration and exploitation of all power stations is promoted.

### Experimental Setup

The main experiment of this work is a two-stage scenario that we refer to as the change experiment: a randomly generated population is first evolved in one type of environment for a certain time, then the environment changes and the adaptation in the second stage is measured. Compared to using only a single stage, our preliminary runs have shown that this reduces the bias from choosing how the initial population is constructed and variance in the results. The two environments are created by changing the appearance of the power stations. In the first stage, the power stations blink in red, a unique colour signal in the arena and thus an easy challenge. After two million ticks, the colour changes to blue, which is the same colour as other robots and difficult to distinguish because the temporal change of the blinking signal has to be detected. We have shown with the same neuron model that the second stage requires recurrent connections and hidden neurons whereas top performance is possible in the first stage without hidden neurons (Schwarzer et al., 2011). The experiment continues for 4 million ticks in the second stage for a total of 6 million ticks.

In a second experiment, we test if different speeds of environmental change have an effect. The environment is

Figure 4: Development of collection performance of the change experiment. After the colour change at 2 million ticks, the performance drops sharply but the system re-adapts and performance recovers.

gradually changed by continuously altering the colour of the power stations by increasing the hue in HSV colour space at maximal saturation and brightness, starting with plain red. This leads to a continuous, repeating cycle through fully saturated colours. By changing the time for a full colour cycle, the speed of environmental change can be varied. The experiment lasts for 6 million ticks and we refer to this experiment as the colour cycle experiment.

The initial population for both experiments is generated with random genomes that encode a fully connected network with hidden neurons. All link weights are uniformly randomly initialized with values between  $\pm 0.2$ . One chromosome contains all necessary genes for these structures, it has twice as many gene sites as genes and they are placed on random sites. In addition to the genes for the connected network, six disconnected node genes are added so that treatments with zero initial neurons can still evolve them. In order to obtain a diploid genome, a mutated homologue copy of the first chromosome is added.

The mutation rate is controlled by the mutation factor on the genome. We let this mutation factor evolve slowly but also run trials with a fixed value. The number of initial neurons is varied, which affects the degree of structural evolution needed and the number of initial genes. Since the initial neurons are fully connected, the genome size increases quadratically with more neurons. The colour cycle experiment varies the time needed for a full colour cycle. See Table 1 for an overview of all experimental factors.

The response variable of both experiments, called (collection) performance, is the mean of all evaluations of all four robots in a time frame of 500,000 ticks. It is a fairly long

time, encompassing a total of 800 individual evaluations, in order to reduce variance. The theoretical maximum performance is 40, limited by the recharge rate of the power stations. Fifty replicates were done in all factor combinations.

## Results

Recombination naturally outperformed in the lower mutation factors of 0.031 and 0.125 but at these levels the absolute performance was also reduced. At higher mutation levels, the differences between pure mutation and recombination are small. The effect of the error threshold comes into play only with higher initial network sizes, and thus large genomes. With 0 initial neurons (32 initial genes per chromosome), performance is still high even with mutation factor of 32 whereas with 14 neurons (458 genes) some treatments have reduced performance at factors 8 and higher (shown in Figure 5). Evolving the mutation rate reduced this pattern only slightly. We use in the following result presentation the treatment with 14 initial neurons as a baseline because it shows the biggest differences. The adaptive mate choice generally settled at a low recombination rate of 14.7% ( $s = 16.8\%$ ).

The asterisk in the graphs indicate significance levels ( $p \leq 0.05$ : \*,  $p \leq 0.01$ : \*\*,  $p \leq 0.001$ : \*\*\*) of a two treatment comparison using Wilcoxon signed rank test with  $n = 50$ . Outliers in the box and whisker plots are more than 1.5 interquartile ranges outside of the box. The data was analysed using R Version 2.15.2 (R Development Core Team, 2011).

Figure 5: End performance of the change experiment with adaptive mate choice, adaptive mutation rate and 14 initial neurons. The effect of various mutation rates can be seen with an optimal rate between 1 and 8. In this configuration, recombination outperforms also at the elevated mutation factor of 8.

### Environmental Change Experiment

The two stages of the change experiment can be seen in Figure 4 where the development of performance over time is shown in the treatment with adaptive mutation rate and 14 initial neurons. After two million ticks, the performance drops sharply when the power stations switch their blinking colour from red to blue. The swarm re-adapts to the new situation and performance rises.

A comparison of collection performance at the end of the change experiment with 14 initial neurons, adaptive mate choice and adaptive mutation rate across mutation rates is shown in Figure 5. This is the only configuration where recombination significantly outperformed in mutation factors of 1 and higher ( $p \approx 0.114$  at factor 1,  $p \approx 0.004$  at factor 8).

This peculiarity is illustrated in Figure 6 where the relative performance of recombination versus pure mutation is shown across alternative configurations. (A) repeats the boxplots from Figure 5 at a mutation factor of 8, the other shown configurations keep this mutation factor and change one other experimental factor. In (B), random mating is shown instead of the adaptive mate choice. Random mating is actually performing better at low mutation rates, but at higher rates the results drop off to significantly lower levels than no recombination ( $p \approx 0.019$ ). The adaptive mutation rate is disabled in (C), the general performance drops and the significant difference between the two treatments disappears as well. In (D), 0 initial start neurons are used and end performance reaches peak levels but no significant difference are present. Thus, the advantage of recombination at high mutation levels is only seen with large networks, adaptive mutation rate and adaptive mate choice. However, the adaptive mate choice also never performed worse than without

Figure 6: Comparison of the end performance of the change experiment with an elevated initial mutation factor of 8 in other configurations: (A) Same as Figure 5. (B) Random mating instead of adaptive mate choice. (C) Fixed mutation rate instead of adaptive rate. (D) 0 initial neurons instead of 14.

any recombination. Whereas random recombination suffers at high mutation rates and pure mutation suffers at low rates, the adaptive mate choice always reaches top performance.

We found an unexpected result when looking at the sizes of evolved neural networks, shown in Figure 7. Recombination treatments evolved generally smaller networks with fewer neural links. We find strongly significant differences for most of the parameter space we investigated, except in the most extreme mutation rates.

### Colour Cycle Experiment

The different rates of change in the colour cycle experiment have an inconclusive effect. End performance is similar across cycle times despite the large range of values covered. This can be seen in Figure 8 where the results with 14 initial neurons, initial mutation factor of 8, adaptive mutation rate and adaptive mate selection is shown. At the lowest colour cycle times of 100.000 ticks, the appearance of the power stations changes from one primary colour to the next within 14 evaluations but the system tolerates this rapid change well.

We find significant stronger performance of recombination at cycle time of 250.000 ( $p \approx 0.008$ ), 1.000.000 ( $p \approx 0.031$ ) and 2.000.000 ticks ( $p \approx 0.031$ ) but not at 100.000 and 500.000 ticks. As before in higher mutation rates, random recombination is significantly worse than the other two treatments. The resulting network sizes are also significantly lower here for recombination treatments, shown in Figure 9.

### Discussion

At the optimal mutation rate for the given scenario, pure mutation achieves similar performance as recombination. Random recombination virtually increases the effect of muta-

Figure 7: End link count of the neural networks in the change experiment. Recombination leads to smaller networks than no recombination except under extremely high mutation rates.

tion: compared to pure mutation, it has good performance at lower rates but suffers from increased mutation rates sooner. This agrees with the findings of Ochoa and Harvey (1999) where recombination reduced the error threshold. The reduced performance at higher mutation rates with larger initial networks is also similar to the results in Ochoa (2006) where the error threshold was lowered with increased genome length.

The adaptive mate choice mechanism, however, has always a strong performance and is robust to different mutation rates. It significantly outperforms in high mutation rates when the mutation rate itself can evolve and when using larger neural networks. This could be related to the effect of the error threshold as originally described in evolutionary biology: as genomes become larger, maximal mutation rate has to be reduced (Eigen, 1971). Our results indicate that recombination might be able to compensate for the reduced maximal mutation rate with selective mating strategies. And it is likely that better results are possible with more sophisticated mating selection.

Finally, the effect that recombination produces smaller networks is interesting since there are no direct costs for network size in the system. Also this seems unrelated to the effect of genome size as mentioned before because it is much stronger than the differences in performance. Also only the neural network is reduced; the number of genes stay roughly the same but the number of junk genes is increased. Large networks likely exacerbate the problem of network crossover, which is biggest for the random recombination treatment that also produces the smallest networks. Although the network size had no effect on performance here, smaller networks could easily be considered an advantage in terms of lower computational costs.

Figure 8: End performance of the colour cycle experiment. There is little effect of the different rates of colour change. Adaptive mate choice sometimes outperforms no recombination.

## Conclusion

In our simulated experiment about the online evolution of neural networks for swarm robots, we found that the difference in performance between pure mutation and recombination depends largely on the mutation rate and the size of the neural network. With the optimal mutation rate, omitting recombination achieved similar performance, but outside of this rate, recombination did outperform, in particular with large networks and adaptive mate selection. Since it can be difficult to estimate the optimal mutation rate before deploying a system, the robustness to suboptimal mutation rates can be an advantage.

Because recombination is not generally outperforming, our results contrast the conventional practice of generally including recombination in evolutionary algorithms and it might be worthwhile in some situations to omit it. The results are also an indication that the discussion in evolutionary biology about the benefits of sex is not completely unrelated to evolutionary computation. While recombination in evolutionary algorithms does not have the same costs of reproduction like sex in biology, it does suffer from genetic disruption due to breaking of favourable gene combinations, in particular with random recombination. We have shown that a mate selection strategy can mitigate this effect to improve recombination and outperform pure mutation even at elevated mutation rates. This advantage could become even bigger when our artificial organisms require larger, more complex genomes to handle more diverse environments.

## Acknowledgments

## Abstract

Agents controlled by a swarm algorithm interact with each other so that they have collective capabilities that a single agent does not have. The bio-inspired swarm-algorithm “BEECLUST” has the aim to aggregate a swarm at the global optimum even if there are several local optima (of the same type) present. But what about gradients produced of different stimulus types? In this paper, we present the concept of “social stimuli”. We investigate how robots controlled by the BEECLUST-algorithm react to a social stimulus which is created by placing immobilized robots in the environment. It shows that the robots controlled by the BEECLUST-algorithm are able to react on a social stimulus within an environment with a global and a local optimum.

## Background & Motivation

A swarm intelligent system is based only on a few simple rules which lead to a complex collective behaviour (Beni, 2005). Nature provides many swarm intelligent systems for us, where we can adopt algorithms. In earlier experiments such swarm intelligent behaviour of young honeybees was investigated. The preferred temperature of young honeybees is 36°C which is also the main temperature in the brood nest of a bee-hive (Grodzicki and Caputa, 2005; Heran, 1952). This temperature is very important for the development of young honeybees and can be interpreted as a natural mechanism to confine them to the brood nest.

In previous experiments it was found that a single young honeybee (*Apis mellifera*) is mostly not able to locate the area with its preferred temperature, whereas a group of young honeybees is able to find the right spot collectively (Kernbach et al., 2009; Schmickl et al., 2008). Figure 1(a) and 1(b) show example-results from such experiments. Similar pictures are shown in (Bodi et al., 2012). From this swarm-intelligent behaviour an algorithm was derived: the BEECLUST algorithm (Kernbach et al., 2009). This algorithm is used in autonomous swarmrobots to find the global optimum out of several local optima. Such optimum could be a light gradient or - in our case - a temperature gradient. What makes the BEECLUST algorithm special is that it has only a few requirements: The robot needs

| Not Needed                               | Requirements                                                 |
|------------------------------------------|--------------------------------------------------------------|
| no explicit communication                | sensors for distance-measurement                             |
| no permanent measurement of the gradient | one single non-directional sensor for measuring the gradient |
| no memory                                |                                                              |
| no ego-positioning                       |                                                              |
| no knowledge of the environment          |                                                              |
| no complex navigation (only random-walk) |                                                              |

Table 1: Requirements and non-requirements of the BEECLUST algorithm

infrared sensors for distance-measurement and a sensor for measuring the gradient (eg. light- or temperature-sensors). Thus, robots controlled by the BEECLUST algorithm do not need or use abilities that are essential for many other robot-algorithms (table 1).

As there are only a few requirements, the algorithm is used more often in robot swarms in the last years (Schmickl et al., 2008; Kernbach et al., 2009; Kengyel et al., 2011; Arvin et al., 2011). The algorithm is also analysed very well by theoretical models (Hamann et al., 2012; Schmickl and Hamann, 2011; Schmickl et al., 2009; Hereford, 2010).

This paper deals with another feature of the BEECLUST algorithm: “Can the decision-making be influenced by an additional kind of gradient?” An easy way to create a second kind of gradient is to place immobilized agents into the arena and thus creating something we define as “social gradient”. In the BEECLUST algorithm there is only a minimal social component modelled which is the discrimination of an obstacle and another agent. However, we assume that the system reacts on the social stimulus without changing the original algorithm and therefore the minimal social component plays an important role.

(Acerbi et al., 2007) showed that a social component can improve the success of algorithms based on genetic evolution or individual learning. An experimental setup was created artificially to analyze the social component in the BEECLUST-algorithm: Although the optima are typically not known a priori, immobilized agents were placed into the suboptimum allowing us to understand the effects of the social component of the algorithm. By investigating this behaviour our goal is to create new hypotheses for the swarm research of young honeybees and other social species. Please note, that these experiments aim for an improved understanding of the BEECLUST algorithm and not improvement of the efficiency.

A short description of the BEECLUST algorithm is provided here, for details see (Kernbach et al., 2009; Schmickl et al., 2008). The algorithm works as follows:

1. The agents move around randomly until the agent detects an object in the front.
2. If there is an object, the agent has to distinguish between a collision with an obstacle or another agent:
  - (a) If the agent collided with an obstacle, the agent turns around and moves randomly again.
  - (b) If this is an agent-to-agent-approach, both agents measure the temperature and calculate the waiting-time which is dependent on the temperature.
3. If the waiting-time is over, the agents move around randomly again.

In the experiments described in (Kengyel et al., 2011; Kernbach et al., 2009; Schmickl et al., 2008), the BEECLUST algorithm was derived and tested with a single kind of gradient: a light- or temperature-gradient. The agents, regardless of the type of agents, were always able to determine the global optimum. In (Schmickl et al., 2008) the algorithm is also tested with two gradients of different intensity and also in dynamically changing environments, showing that the algorithm is flexible enough to react on these dynamic changes of the environment. The cooperation of two swarms with different waiting time curves is investigated: It is shown that the two swarms benefit from the cooperation with each other if there is only a small swarm (Bodi et al., 2012).

In this work we present the results of experiments in which we investigate how a second, different kind of gradient influences the decision-making of the bio-inspired swarm-algorithm. This paper deals with the following questions:

1. Is the clustering behaviour of the BEECLUST algorithm sensitive to a social gradient?

2. Does a swarm have to trade off between two different gradients?
3. How many social agents are necessary to influence the aggregation behaviour?

## Material & Method

We implemented the BEECLUST algorithm in a simulation environment and designed experimental settings that allows us to answer the questions.

### Implementation of the Algorithm

For the simulation we used a free multiagent simulation-platform in which we modelled the bio-inspired swarm-algorithm simulating the individual honeybees as autonomous agents. In this work we use a simplified simulation of a robot swarm controlled by the BEECLUST algorithm.

**Sensormodel** As the algorithm is derived from the behaviour of young honeybees we modelled their antennae for the measurement of temperature as follows: Each position in the arena has a specific temperature assigned (see section “Experimental Setup”). If an agent has to measure the temperature, it has to interrogate the temperature of its current position. This ensures an easy and efficient way to map a temperature and its measurement from an agent’s point of view. See section “Calculation of Waiting-time” for more detailed information.

As BEECLUST experiments were conducted with robots in (Schmickl et al., 2008) we modelled robots’ sensors for the distance measurement. Each simulated robot has three sensors: one in the front, one on the left and one on the right side. Each sensor has an aperture angle of 90°, so that the agent has a field-of-view of 270°. One robot has a diameter of 8 cm. To simulate the distance-measurement of robots we convert the measured distance into integer-values from 0 to 255. The visibility-range of an agent is about 1.5 robot-diameters. According to this a distance of 1.5 robot-diameters is mapped to a value of 0 and a distance of 0 robot-diameters results in a value of 255. A uniformly distributed random noise of [0;10] is added to the measurement.

| Temperature | Waiting-time |
|-------------|--------------|
| <26°C       | 0s - 10s     |
| 26°C - 29°C | 18s - 40s    |
| 29°C - 33°C | 18s - 80s    |
| >33°C       | 90s - 130s   |

Table 2: Dependency of local temperature and the waiting-time of the agent

(a) Bee-arena with bees at the beginning of the experiment. Left side: local optimum with 32°C, right side: global optimum with 36°C.

(b) Bee-arena with bees at the end of the experiment. Bees are clustering at gray area is the local optimum with the global optimum at 36°C on the right side.

(c) Setup of the arena. The left light-gray area is the local optimum with a temperature of 30°C - 32°C and on the right side the dark-gray area indicates the global optimum with a temperature of 30°C - 36°C. The black circle inside of the arena shows the area where the agents (black triangles) are released at the beginning of the experiment.

Figure 1: Experimental setup of bee experiments (left and middle) and similar experimental setup for robots (right).

**Calculation of Waiting-time** Choosing the right waiting time for specific temperatures is one of the most important parts of the BEECLUST algorithm. Kernbach et.al. (Kernbach et al., 2009) measured the waiting-time of bees after a bee-to-bee-approach dependent on the temperature of the bees' current position. Based on these measurements the waiting-time in the simulation is chosen as follows: For a temperature less than 26°C, the waiting-time is chosen randomly between 0s and 10s, for temperatures between 26°C and 29°C the agents' waiting-time is between 18s and 40s and for temperatures between 29°C and 33°C a waiting-time from 18s to 80s is chosen. For temperatures above 33°C the calculated waiting-time is between 90s and 130s (table 2).

**Experimental Setup** The experimental setup is based on an arena that was built for monitoring the behaviour of young honeybees in a complex temperature gradient (Szopek et al., 2008; Bodi et al., 2012). Figure 1(a) and 1(b) show the setup of the bee-arena. Figure 1(c) shows the robot-arena which has similar experimental setup. The arena has a diameter of 25 agent-lengths. It is surrounded by a wall in which the agents are able to perform their movements. On the left and on the right side there are two heat sources which create two different temperature-gradients (light- and dark-gray areas in figure 1(c)): The global optimum with a maximum of 36°C is located on the right side of the arena and occupies an area of about 11% of the arena. The temperature gradient ranges from the right side with 36°C to the middle of the arena with 22°C. The local optimum is located on the left side of the arena and occupies as well 11% of the arena. Here the maximum

temperature is 32°C on the left side and ranges to the middle of the arena with 22°C. The 30°C threshold is defined as the border of the local and the global optimum. 78% of the area (white area inside of the arena in figure 1(c)) is defined as the pessimum and has a temperature of 22°C in the middle of the arena.

To test the hypotheses we designed four different experiments (figure 2):

- (1) This experiment is used as a reference-experiment. Here we test the BEECLUST algorithm for the given arena with the global optimum on the right side and without the suboptimum on the left side (figure 2(a)).
- (2) In this experiment we additionally provide the suboptimum on the left side of the arena (figure 2(b)).
- (3) To test how a social stimulus affects the behaviour of aggregation in experiment 3 we place immobilized agents in the suboptimum with 32°C and a dummy-agent in the global optimum with 36°C to avoid side-effects (e.g. jamming-effects) (figure 2(c) and 2(d)). This experiment is conducted with different numbers of social agents to demonstrate how the system reacts to different sizes of a social gradient:
  - (a) with 1 agent acting as a social gradient (as depicted in figure 2(c)).
  - (b) with 2 agents
  - (c) with 3 agents and
  - (d) with 4 agents (as depicted in figure 2(d)).

Figure 2: Different experimental settings. The dark-gray area on the right side of the arena indicates the global optimum with a temperature of  $30^{\circ}\text{C}$  -  $36^{\circ}\text{C}$ . The light-gray area on the left side is the local optimum with  $30^{\circ}\text{C}$  -  $32^{\circ}\text{C}$ . The black triangles indicate agents that are controlled by the BEECLUST algorithm.

Each experiment was repeated 100 times. At the beginning of each experiment the agents are placed randomly inside a central area which has a diameter of 10 agent-lengths and is located in the middle of the arena (figure 1(c)). In all six experiments 15 agents perform the BEECLUST algorithm with identical parameter settings. The agents move around in the arena with a speed of two agent-lengths per second. Agents which generate the social stimuli are immobile and do not perform the BEECLUST algorithm. To ensure that placing agents into the suboptimum has no side-effects (e.g. regarding jamming-effects due to overcrowding of an optimum) we also place dummy-agents into the global optimum which are perceived as obstacles and not as an agent.

**Changes to the original BEECLUST Algorithm as published in (Schmickl et al., 2008)** The BEECLUST algorithm is not changed in its sequence, only the input values for calculating the waiting time mentioned in table 2 where taken from a temperature gradient instead of a light gradient. We didn't have to adapt the algorithm so that it responds to the social gradient.

## Results

On the x-axes of figure 3 and 6 the abbreviation "LO" is referring to experiment (2) with only a global and a local optimum. "1SA", "2SA", "3SA" and "4SA" are referring to experiments with a social gradient with 1, 2, 3 or 4 social agents, respectively.

Figure 3: Percentile of time the agents spent in the global optimum. The plot shows the median with 1<sup>st</sup> and 3<sup>rd</sup> quartile.  $n=100$ . The bars with asterisks indicate significances at a significance-level of  $p=0.05$  and were tested with the Wilcoxon-Mann-Whitney-U test (nominal scaled).

The time the agents spent in the global optimum is shown in figure 3. In experiment 1 (“GO”) with just one optimum of 36°C the median time the agents spent in the global optimum is 47.88%. The median time in the experiment (2) with a local optimum (“LO”) is 34.98% and with 1 social agent (“1SA”) the median time is 32.62%. The results of experiment 1 is significantly different to the results of experiment 2 and 3a. The significances were tested with a level of  $p=0.05$  (Wilcoxon-Mann-Whitney-U test).

Figure 4 shows the time the agents spent in the global optimum of the experiments with a different amount of social agents. The median times of experiments with 1, 2, 3 and 4 social agents are 32.62%, 30.12% , 27.03% and 28.54%, respectively. Here, the significances were

Figure 4: Percentile of time the agents spent in the global optimum in experiments with an increasing amount of social agents. The statistics is made with Spearman-statistics (ordinal scaled).

tested with Spearman-statistics and showed no significant correlation between the amount of social agents and the time the agents spent in the global optimum ( $p = 0.025$  and  $\rho = -0.112$ ).

Figure 6 shows the percentage of time the agents spent in the local optimum. The time for experiment 1 (“GO”) is calculated with a uniform distribution model, due to the fact that in this experimental setting no local optimum is available. As the defined area of the local optimum covers 11%, the agents would spend 11% of the time in this area. In experiment (2) the median time spent in the local optimum of 32°C was 16.25%. The median time for experiment (3a) with one social agent is 26.50%. The results of the experiments here are all significantly different to each other. The significances were tested with a level of  $p=0.05$  (Wilcoxon-Mann-Whitney-U test).

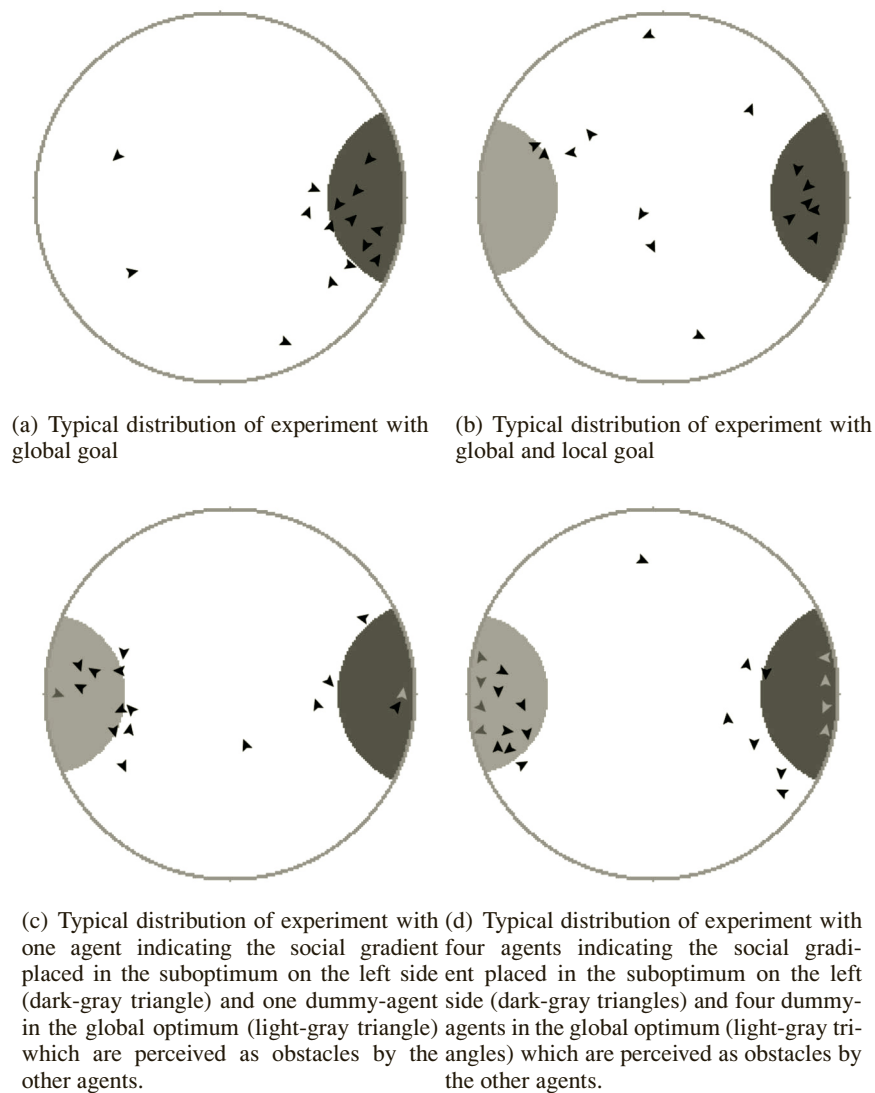

Figure 5: Examples of results of different experimental settings. The dark-gray area on the right side of the arena indicates the global optimum with a temperature of 30°C - 36°C. The light-gray area on the left side is the local optimum with 30°C - 32°C. The black triangles indicate agents that are controlled by the BEECLUST algorithm.

In figure 7 the time the agents spent in the local optimum are shown for the experiments with an increasing amount of social agents. The median times for 1, 2, 3 and 4 social agents are 26.50%, 27.08%, 29.21% and 30.04%, respectively. The significances were tested with Spearman-statistics and showed no significant correlation between the amount of social agents and the time the agents spent in the local optimum ( $p = 0.003$  and  $\rho = 0.148$ ).

## Discussion

The main feature of the BEECLUST algorithm is to find the global optimum within a complex environment, as shown

in (Schmickl et al., 2008) experiments with light-gradients in a dynamic environment were conducted. In the following, we will discuss the three questions mentioned in section “Background & Motivation”:

*Is the clustering behaviour of the BEECLUST algorithm sensitive to a social gradient?*

The BEECLUST algorithm as tested in (Schmickl et al., 2008) is able to locate the global optimum in static and dynamic environments robust. In the experiments we showed that this stable decision-making can be influenced by adding another gradient - a social gradient. By just using one additional agent - functioning as a source of a social

Figure 6: Percentile of time the agents spent in the local optimum. The plot shows the median with 1<sup>st</sup> and 3<sup>rd</sup> quartile.  $n=100$ . The bars with asterisks indicate significances at a significance-level of  $p=0.05$  and were tested with the Wilcoxon-Mann-Whitney-U test (nominal scaled).

gradient - we were able to increase the percentage of time in the local optimum from 16.25% to 26.50% (compare figures 5(b) and 5(c)).

*How many social agents are necessary to influence the aggregation behaviour?*

Adding just one single social agent had a huge effect. We were able to bound agents for more than 10% of the time to the suboptimum. To reach the threshold were the agents spend more time in the suboptimum than in the global optimum, three social agents were necessary (see figure 4 and 7). This leads us to the next question:

*Does a swarm have to trade off between two different gradients?*

A swarm of agents which is controlled by the BEECLUST algorithm always decides for the global optimum even if a second suboptimal gradient of the same type is present. Thus a discrimination of the local and the global optimum

Figure 7: Percentile of time the agents spent in the global optimum in experiments with an increasing amount of social agents. The statistics is made with Spearman-statistics (ordinal scaled).

is possible. If there is a second gradient of another type, the decision-making of a swarm is not that clear anymore. In a weak gradient, agents which were undecided start to decide for the social gradient, but also agents from the global optimum reconsider their decision. If the social gradient gets stronger, no more agents are bound from the pessimum but some additional agents from the global optimum change their minds (see figure 5).

The percentage of time that agents spent in the pessimum is significantly lower in the experiments with social agents (3a, 3b, 3c) compared to the experiment without a social stimulus (2). Increasing the amount of social agents had no significant effects.

If we compare the results of experiment (3a) with experiment (2) it appears that fewer agents stay in the pessimum or global optimum and more agents stay in the local optimum. We can conclude that agents get bound not only from the global optimum but also from the pessimum (figure 3

and 6). This effect can also be observed in the results of experiment (3b). Three social agents is the minimum number of agents that are needed so that more agents place themselves in the local optimum than in the global optimum (figure 4 and 7). Adding another social agent - in total 4 social agents - leads to no significant changes in the percentage of time the robots spent in the optima.

## Conclusion & Future Work

We conclude that the BEECLUST algorithm can be influenced by using a social gradient induced by immobile agents placed in the suboptimal area of the arena.

As the social gradient had an unexpected big effect, we also want to introduce the social gradient to experiments with real honeybees. As the BEECLUST algorithm is derived from the behaviour of young honeybees, we expect that the decision-making of young honeybees can also be influenced by offering a second, different type of gradient. These results can then be used for further investigations of the swarm-intelligent behaviour of honeybees by creating bio-hybrid systems consisting of real honeybees and artificial autonomous robots (Schmickl et al., 2013).

In (Schmickl et al., 2008) robot-experiments were conducted in light-gradients. We want to implement the BEECLUST algorithm in robots and expose them to a temperature-gradient and a social gradient. With this, we want to get closer to the situation honeybees are faced with and provide feedback for the biological swarm research.

## Abstract

In this paper we study the time delays affecting the diffusion of information in an underwater heterogeneous robot swarm in a time-sensitive environment. In many situations each member of the swarm must update its knowledge about the environment as soon as possible, thus every effort to expand the time horizon is useful. Otherwise critical information may not reach nodes far from the source causing dangerous misbehaviour of the swarm. We consider two extreme situations. In the first scenario we have an unique probabilistic delay distribution. In the second scenario, each agent is subject to a different truncated gaussian distribution, meaning local conditions are significantly different from link to link. We study how several swarm topologies react to the two scenarios and how to allocate the more efficient transmission resources in order to expand the time horizon. Results show that significant time savings under a gossip-like protocol are possible properly allocating the resources. Moreover, methods to determine the fastest swarm topologies and the most important nodes are suggested.

## Introduction

The robotic technology in ocean surveys, inspections, monitoring, pipe and cable tracking, has been well established in marine engineering (Leonard, 1998) with an important increase in performance in recent years (Nawaz, 2005).

Today, an AUV (Autonomous Underwater Vehicle) must be considered (Dell'Erba, 2012) as a real cost alternative to other available technologies, such as manned submersibles, remotely operated vehicles and towed instruments led by ships.

A group of underwater robots resembles closely a fish swarm, suggesting to use the properties of the biological swarm: coordinated movements, decentralized control, small interaction scale, minimal information broadcast.

The biologically inspired swarm control has advantages over the more complex but single robot: it covers a larger area, is fault tolerant, is self-aware. But it needs an inter-swarm information exchange and consequently delays in the information spread are generated (Beni, 1989).

However, communication channels are a major concern, as the acoustic underwater transmission is very slow and bandwidth limited, but, in the future, optical, high power transmission devices will be available for a number of different approaches integrating the acoustical data channel. Although optical methods are very powerful their

performances are affected by many strongly variable parameters like temperature, depth, salinity, turbidity, the presence of dissolved substances that change the colour and the transparency in different optical bands and the amount of solar radiation that heavily affect the signal to noise ratio. Moreover, horizontal underwater channels are prone to multipath propagation due to refraction, reflection, scattering.

The low speed of sound is also at the origin of significant Doppler effects, divided in frequency shifts and instantaneous frequency spreading contributing to the Doppler variance of received communication signals (Otnes, 2011).

Another important issue is the energy consumption, that requires optimization techniques to prevent batteries early exhaustion.

Nevertheless, the acoustic option for underwater data transmission is still the state-of-the-art methodology, and in this paper we will refer to it. To accomplish the above tasks it is necessary to control many submarine robots simultaneously, therefore researchers consider worthwhile to use biologically inspired models.

The swarm has advantages over the more complex but single robot usage: it covers a larger area, is fault tolerant. But it needs a heavy inter-swarm information exchange and consequently delays in the information spread.

## Goals

Depending on the local underwater environment, the speed of acoustic waves in water varies around 1500 m/s. The other source of delay is the management of the acoustic channel by proper MAC (medium access control) protocols (Otnes, 2011).

In this paper, we focus on the reduction of delays when the fast propagation of short warning messages to the whole swarm is needed. We consider the existence of a small group of AUV equipped with high quality communication devices able to reduce the transmission time with their closest neighbours.

Then the point is how to allocate these AUV into the suitable swarm configurations to obtain the largest time savings, extending the time horizon of the swarm.

To this end, we borrow from the graph theory some methods able to identify the most critical nodes with respect to the information transfer and test them numerically on several swarm configurations by means of Markov chains.

Figure 1: The swarm configurations. From top left: E-R, S-W, Cluster, Grid, Galaxy. Graphs have been modified with respect to the standard topologies. Bottom right: a single star.

Technical details of transmission underwater devices are out of scope, but can be found in a number of papers, for example see (Pompili, 2006), (Pompili, 2010) and (Burrowes, 2011).

## Scenarios and Data Preparation

### The Simulation Scenarios

Two scenarios are studied. In the first (scenario I), all delays are derived from an uniform probability distribution. In the second (scenario II), each link between two nodes is affected

Figure 2: Left, delays uniform distribution (scenario I); right, delays positive support Gaussian distribution (scenario II).

from its own Gaussian distribution with positive support, because delays are strictly positive (Mazet, 2012).

A different probability distribution for each node pair  $i \rightarrow j$  has been implemented recently by (Picu, 2012), but not many researchers adopt this hypothesis, because of the analytical intractability of the mathematical related model.

Although we do not assume an explicit statistical dependence among links departing from the same node, we acknowledge the existence of a dependence (Chakrabarti, 2008) among processes that govern the delays (Xia, 2008). On the other hand, MAC protocols clearly indicate such dependences. This element is important because it rules out the usage of the Central Limit Theorem in the calculation of the overall graph delay and make it necessary the heuristic approach as opposed to the analytic approach.

The numerical values of the simulation have been elaborated according to a worst – case criterion from (Pompili, 2006); they cannot be considered typical of delays encountered in the underwater environment, as its variability and non stationarity are so wide to prevent any attempt, but can represent a reasonable case study. Also the Gaussian nature of the delay distribution is to be considered an approximation of reality, as statistics are sorely lacking.

The other major source of delay, the speed of the acoustic waves in water is taken into count in the simulation model, but in the scenario I the physical distances among nodes are fixed (150 m) while in scenario II may vary (150 – 225 m).

### The Configurations

The configurations assumed by the AUV (in the following called graphs or networks) considered in this paper are the random Erdos-Renyi (E-R), a graph whose nodes are connected almost randomly; the Grid, a regular disposition of nodes; the Small-World (S-W), a configuration between the grid and the random graph; the Galaxy, a group of interconnected star configurations; the Cluster, a group of interconnected ring configurations.

Note that in order to have the same number of links and node for all graphs, the basic structure of the graph has been modified adding/removing links. Hence, graphs of Figure 1 *do not resemble exactly* the standard topology of a small-world, a grid or a cluster.

Moreover, the links represent the acoustic communication channel between two nodes in a logical way, therefore the

geometrical form of graph in Figure 1 may change in the real environment, without loss of generality. These links are stochastic variables, meaning they may disappear randomly; their Euclidean length in the scenario I is set to 150 m, while in the scenario II can vary between 150 – 200 m, depending on a stochastic variable (if the link exists).

### The Optimization Methods

The number of the algorithms and of parameter devised to study graphs from the topological point of view is very large. Here we are interested in those who can determinate a small set of nodes (the “budget”) equipped with particular spreading influence. The phenomenon is analogous to the diffusion of a malware or a real virus. It is known (Arbore and Fioriti, 2013) that some nodes are more “important” and may facilitate or prevent the spreading. In most cases it is not a trivial task to find the influential nodes in large graph, but fortunately AUV swarms are reduced to less than a few hundreds. Nevertheless useful insight may be gained even with just one hundred of nodes, as in the present case.

The methods we use are: AV11, degree centrality, betweenness centrality and finally the random choice (in order to check results against the banal predictor). Others parameter are available, but these are probably the more relevant to our investigation. The degree centrality is the simplest algorithm. It suffices to count the number of links connected to a node. It is also intuitive that an high degree designate an “influent” node (called hub).

Betweenness centrality (BC): total number of shortest paths between every possible pair of nodes that pass through the given node. Betweenness looks for vertices connecting separated subgraphs (Newman, 2010), therefore high BC nodes may be understood as a sort of bridges.

AV11: selects a subset of  $k$  nodes all at once, according to spectral combinatorial methods. The selected subset may be optimal or suboptimal with respect to the brute-force method (Arbore, 2011). Spectral methods are able to analyze the dynamical behavior of graphs from the static appearance of the topology.

The algorithms identify ten nodes: for example, the degree centrality selects the upper row of nodes below and the AV11 the second row:

31, 21, 6, 61, 71, 81, 41, 91, 1, 51  
31, 21, 6, 61, 56, 81, 76, 36, 45, 15

in the case of the Cluster graph.

Once the set is identified, a high quality transmission AUV is assigned to the nodes of the graph. We simulate this operation assigning smaller delay capability to the links departing from the “optimized” node, i.e. optimally allocating the resources.

### The Protocol

The protocol we consider here is a gossip – like (sometimes called “epidemic spreading”) protocol, i.e. each node-agent in the swarm broadcasts the message to the one-hop neighbour.

The diffusion process is started by one node and must reach every node of the swarm within a finite time (the time horizon). In this paper we follow a number of specifications for the protocol, namely:

- the transmitting node contacts the receivers following the numeration priority rule (node  $j$  is contacted before node  $j+1$  (only single transmission are allowed);
- agents know only their neighbours;
- the receiving node has no previous knowledge of the message to be delivered;
- the link between two nodes  $i \rightarrow j$  is fixed, but the on/off status depends on a stochastic variable;
- if a link is off, no attempt to transmit is made;
- all particular delays due to MAC parameters are included into the stochastic delay characterizing the  $i \rightarrow j$  link;
- apart from re-transmitting the message eventually, no elaboration takes place inside the agent on the message data;
- the QoS (quality of service) of the communication link is completely described by the delay.

In practice, it is assumed the transmitting node contacts one neighbour at a time, sequentially.

This protocol is quite general to encompass many actual protocols. It is configured to serve as warning signalling tool, therefore the message to be transmitted is short (64B).

## Simulation Results

Numerical simulations have been conducted till stable results have been obtained. In Table 1 are shown the delays in the two scenarios. Absolute times should not be regarded as indicative of a general behaviour, because of the too wide variation of the conditions in the real marine environment. The important point here is the relative time difference among the topologies in each scenario. However, Table 1 shows that the variances are small and similar, hence the numerical experiments are reliable.

| Graph   | Average delay I | Delay Var. I | Average delay II | Delay Var. II |
|---------|-----------------|--------------|------------------|---------------|
| E - R   | 23.29           | 2.22         | 26.68            | 3.15          |
| S-World | 23.33           | 2.37         | 26.64            | 2.85          |
| Galaxy  | 23.32           | 2.16         | 25.70            | 3.00          |
| Grid    | 23.35           | 2.25         | 25.77            | 2.71          |
| Cluster | 23.34           | 1.87         | 25.75            | 2.86          |

Table 1: First two columns: overall delays and variances for different topologies with unique distribution scenario I (without optimization). Last two columns: overall delays and variances for different topologies (without optimization) in the multiple distributions scenario II. The time unit is the second.

In Table 2 the spectral analysis of the five topologies is presented. We rank them according to three well-known parameters of the spectral graph theory: the maximum eigenvalue of the adjacency matrix of the graph,  $\lambda_n$ , the spectral gap  $\lambda_{n-1} - \lambda_n$  of the laplacian matrix, and the algebraic connectivity  $\lambda_2$ , the first non zero eigenvalue of the laplacian matrix, given the ascending ordering:

$$\lambda_1 < \lambda_2 < \dots \lambda_{n-1} < \lambda_n$$

A large value of these parameters describe the connectivity of the graph, the lack or presence of isolated components, the lack or presence of bottlenecks (Restrepo, 2006) and (Van Mieghem, 2011). Information in well connected graph travel easily and the probability that a node may remain disconnected is lower, two important issues for AUV swarms.

The maximum eigenvalue of the adjacency matrix and the spectral gap are in complete accordance with the largest percentage reduction in the reduction of the overall delays (described in Table 3 and 4), while the algebraic connectivity differs only for the misclassification of the Grid and the Small-World topologies.

Therefore, the spectral analysis is also able to predict those swarm topologies prone to realize a major delay improvement allocating the best transmission resources in the nodes suggested by one of the topological algorithms.

Now, there is a trade-off on the largest eigenvalue of the adjacency matrix in the consensus problems of Olfati-Saber. According to (Olfati-Saber, 2004 and 2007) the stability of a fixed configuration is guaranteed iff:

$$\tau \leq \pi / 2\lambda_{max} \quad (1)$$

where  $\tau$  is the uniform delay experienced by the consensus distributed computations and  $\lambda_{max}$  is the maximum eigenvalue of the adjacency matrix.

Similar constraints may be set for non uniform switching topologies. The delay  $\tau$  depends on a number of factors: CPU power, data transmission bandwidth, MAC protocols, the number of AUV  $N$ , the inter-symbol interference. Clearly, it is convenient a small  $\lambda_{max}$ .

But, at the same time, we need to have a large  $\lambda_{max}$  to take advantage of the delay reduction in message transmissions. The spectral analysis of Table 2 therefore helps in determining the effect of  $\lambda_{max}$  on the delays.

| Graph   | Max Adj eigenval | Spectral Gap | Algebraic connectivity |
|---------|------------------|--------------|------------------------|
| Galaxy  | 7.9426           | 4.56030      | 0.16927                |
| Cluster | 5.1077           | 1.79950      | 0.12621                |
| E - R   | 3.9286           | 0.77056      | 0.10797                |
| Grid    | 3.4687           | 0.23352      | 0.01066                |
| S-World | 3.3473           | 0.15720      | 0.05807                |

Table 2: Spectral characteristics of the graphs examined. All graphs are of 100 nodes and 140 edges, 2.8 average degree. Simulations were at least of 1000 runs. All graphs are of 100 nodes and 140 edges. Topologies have been modified adding/removing edges to ensure the same number of edges and nodes and the same overall broadcasting delay within a  $\pm 0.2s$  interval. The length of the message to be transmitted is 256 bit in both scenarios.

Table 3 and 4 show the time saving gained using the four methodologies of optimization. Table 3 concerns the scenario I, where a unique uniform distribution provides all the delays between two communicating AUV (nodes of the graph). Only the relative percentage values should be considered, as the absolute values are strictly related to the particular framework examined. It is clear that the Galaxy (group of connected stars) configuration allows the largest delay reduction in both scenarios; furthermore, the star topology (Figure 1, bottom right) is well-known to guarantee good performance and reliability, although expensive.

The classification of the configurations according to the best delay after the optimization considering both scenarios is as follows: Galaxy, Cluster, Erdos-Renyi, Grid, Small-World.

It seems the Galaxy configuration of the AUV acoustic communications is the best by far. It is worth mentioning, anyway, that a star configuration relies heavily on the centre-

star to pass and sort messages, thus dissipating too much energy for the marine environment.

A solution is to alternate the centre-star role among the AUV of the star (Snels and Tabacchiera, 2013), possibly using a frequency coding to avoid signal overlapping, if enough high quality AUV are available. Otherwise the random Erdos-Renyi graph guarantees a good performance in a number of underwater tasks.

| Graph   | AV11                            | Degree                          | BC                | Random             |
|---------|---------------------------------|---------------------------------|-------------------|--------------------|
| E - R   | (15.90)<br>+0.78%               | <b>(15.76)</b><br><b>-32%</b>   | (16.83)<br>+6.7%  | (20.10)<br>+27.5%  |
| S-World | (18.89)<br>+9.3%                | <b>(17.28)</b><br><b>-25.9%</b> | (18.32)<br>+6%    | ((20.37)<br>+17.8% |
| Galaxy  | (9.28)<br>+143%                 | <b>(3.81)</b><br><b>-83%</b>    | (5.00)<br>+31%    | (18.88)<br>+395%   |
| Grid    | <b>(17.38)</b><br><b>-25.5%</b> | (18.75)<br>+7.8%                | (20.07)<br>+15%   | (19.52)<br>+9.16%  |
| Cluster | <b>(15.27)</b><br><b>-34.5%</b> | (16.38)<br>+7%                  | (16.21)<br>+6.15% | (19.90)<br>+30%    |

Table 3: Overall delay for different topologies in the single distribution scenario (I scenario), with optimization. Values within a  $\pm 0.2$  s confidence interval. The optimization techniques are: the AV11 algorithm, the degree centrality, the betweenness centrality and the complete random choice of nodes. Delays are expressed in seconds. Inside the brackets the absolute values. Percentage in bold is the best time saving

Figure 3: Comparison between degree centrality and AV11 for the case of the modified Grid graph. Green node have been selected by both algorithms, red nodes only by degree and blue

node only by AV11. An intuitive selection is not straightforward in this circumstance.

percentage with respect to the overall delays of Table 1 for a given graph.

Now we focus on the performance of the optimization algorithms (degree, AV11, BC and random choice) in selecting the most suitable nodes. Not surprisingly, in both scenarios the degree is the optimal choice in the case of E-R, S-W, Galaxy graph, but AV11 scores -7% with respect to degree for the Cluster and the Grid graph.

Then the simplest of the optimization algorithms (degree centrality) is not always the most successful, as an intuitive reasoning could expect. In fact, the AV11 exceed the degree in the Grid and in the Cluster cases while in the Erdos – Renyi case differences are really minimal.

When the configuration is as simple as the Galaxy (a group of stars) certainly the best choice is obviously the degree centrality parameter, but when the graph is more structured, more sophisticated algorithms such as AV11 are to be considered.

This is an useful finding, as often the static parameter (degree, betweenness, closeness etc.) are not able to identify correctly the influential nodes.

| Graph   | AV11                            | Degree                          | BC               | Random            |
|---------|---------------------------------|---------------------------------|------------------|-------------------|
| E-R     | (17.33)<br>+0.5%                | <b>(17.24)</b><br><b>-35.4%</b> | (18.54)<br>+7.5% | (22.19)<br>+28.7% |
| Small-W | (20.75)<br>+11%                 | <b>(18.68)</b><br><b>-29%</b>   | (20.12)<br>+7    | (22.39)<br>+19    |

Table 4: Overall delays for different topologies with optimization in the multiple distributions scenario (II scenario). The optimization techniques are: the AV11 algorithm, the degree centrality, the betweenness centrality and the complete random choice of nodes. Delays are expressed in seconds. Inside the brackets the absolute values. Percentage in bold is the best time saving percentage with respect to the overall delays of Table 1 for a given graph.

## Theoretical Considerations

Chandra has shown how consensus and broadcasting are reducible to each other also in asynchronous networks with failure detectors (Chandra, 1996). Broadcast allows processes to distribute messages, so that they agree on the set of messages they deliver and the order of message deliveries.

The standard consensus form is:

$$x_i' = \sum_j a_{ij}(x_j - x_i) \quad , \quad j = 1, \dots, N \quad (2)$$

and its delayed version:

$$x_i' = \sum_j a_{ij}(x_j(t - \tau) - x_i) \quad , \quad j = 1, \dots, N \quad (3)$$

where  $a_{ij}$  are the entries of the adjacency matrix  $A$ .

It is known that for a connected network, the equilibrium point for (2) is globally exponentially stable. Moreover, the consensus value is equal to the average of the initial values; for small swarms the average is easy to calculate. In compact form (2) is written:

$$x' = -Lx \quad (4)$$

(2) and similar expressions are utilized in the swarm control to coordinate the states of the robots on a common position/velocity agreement resilient to disturbs (Olfati-Saber, 2007).

Since in the protocol section we have not required synchrony, now we can use the equivalence between the consensus problem and the broadcast problem (consisting in delivering a set of messages in the correct sequence to every agent of the network) to state a sufficient condition (Lu, 2011) for the successful broadcast of a set of subsequent short messages.

Lu shows that asynchronous consensus with stochastic delays can be obtained if during motion the swarm's graph has always had a spanning tree. The same result thus applies equally well to our broadcasting gossip-like protocol.

Recently (Atay, 2013, in press) a necessary and sufficient condition has been obtained for the discrete time, but only for fixed, non-switching links.

## Conclusions

We have examined the delays produced during the information diffusion in an underwater autonomous robot swarm in order to extend its time horizon, properly selecting the swarm configuration and the allocation of high quality transmission devices inside the configuration.

Since the independence condition of variables in the analytical treatment of the delay model cannot be assured generally, numerical simulations have been conducted.

Two scenarios have been simulated. Scenario I considers a unique uniform distribution of delays with fixed inter vehicle

distances; scenario II considers random distances and each link producing a delay, according to a positive support Gaussian distribution (as a delay is an inherently positive quantity). In both cases the links may or may not exist, depending on a uniform distribution probability.

Five swarm configurations (Galaxy, Cluster, Erdos-Renyi, Grid, Small-World) and four allocation methodologies (AV11, degree centrality, betweenness, random choice) have been tested to find the largest time savings.

Results show that the degree centrality applied to the galaxy configuration allows the largest delay reduction in both scenarios, as expected, but only when configuration are dominated by hubs. When the graphs are more structured, spectral allocation algorithms as AV11 are a better choice (Table 3 and 4).

Another useful finding is given by Table 2. The maximum adjacency eigenvalue and the spectral gap reveal the graph capabilities to decrease the delays when optimized.

## Abstract

Evolutionary robotics is heading towards fully embodied evolution in real-time and real-space. In this paper we introduce the Triangle of Life, a generic conceptual framework for such systems in which robots can actually reproduce. This framework can be instantiated with different hardware approaches and different reproduction mechanisms, but in all cases the system revolves around the conception of a new robot organism. The other components of the Triangle capture the principal stages of such a system; the Triangle as a whole serves as a guide for realizing this anticipated breakthrough and building systems where robot morphologies and controllers can evolve in real-time and real-space. After discussing this framework and the corresponding vision, we present a case study using the SYMBRION research project that realized some fragments of such a system in modular robot hardware.

## Introduction

Evolutionary robotics is heading towards fully embodied evolution in real-time and real-space. In this paper we introduce the Triangle of Life, a general conceptual framework that can help build systems where robots can actually reproduce. The framework can be instantiated with different hardware approaches and different reproduction mechanisms. For example, one could use classic mechatronic components and 3D-printing to produce new robots, or a stock of autonomous actuated robot modules as raw material and self-driven aggregation to implement ‘birth’.

The novelty of this framework lies in the pivotal role of reproduction and conception. The life cycle it captures does not run from birth to death, but from conception to conception and it is repeated *in real hardware* thus creating ‘robot children’ over and over again. This is new in evolved 3D printed robots, where the body structure is printed off-line. Even if the design is evolved, the printer only produces the end result after evolution is halted (in simulation), whereas in our framework printing=birth, thus being part of the evolutionary process, rather than following it.

Our approach is also new in self-assembling robot swarms, because existing work traditionally focusses on the transition of a swarm into an aggregated structure (a robot

organism) and vice versa. In the traditional setting, being aggregated is a transient state that enables the robots to meet a certain challenge after which they can disassemble and return to normal. In contrast, we perceive being aggregated as a permanent state and consider aggregated structures as viable robotic organisms with the *ability to reproduce*. That is, two or more organisms can recombine the (genetic) code that specifies their makeup and initiate the creation of a new robotic organism. This differs from earlier work aiming at *self-replication* and *self-reconfiguration* in that a ‘child organism’ is neither a replica of its parents, nor is it a reconfigured version of one of them.

This paper has a twofold objective, 1) to present the Triangle of Life as a conceptual framework for creating ALife of this type and 2) to illustrate how the components of this framework can be implemented in practice. To this end, we will use the SYMBRION research project<sup>1</sup> as a case study, even though originally the project only targeted traditional swarm-to-organism-to-swarm systems, cf. Levi and Kernbach (2010).

## Background and related work

The ideas in this paper can be considered from three perspectives, that of artificial life, evolutionary computing, and (evolutionary) robotics. The modern scientific vision of creating artificial life has a long history dating back to the 1987 Santa Fe workshop, cf. Langdon (1989); Levy (1992); Langton (1995). The most prominent streams in the development of the field are traditionally based on wetware (biology and/or chemistry), software (i.e., computer simulations), and hardware (that is, robots). In this paper we focus on the third option. The main contribution of the paper from this perspective is the introduction of a new, integrative framework, the Triangle of Life, that helps develop and study hardware-based ALife systems. In fact, the Triangle of Life defines a new category of ALife systems and outlines an interesting avenue for future research.

<sup>1</sup>EU Grant number FP7-ICT-2007.8.2, running between 2008-2013.

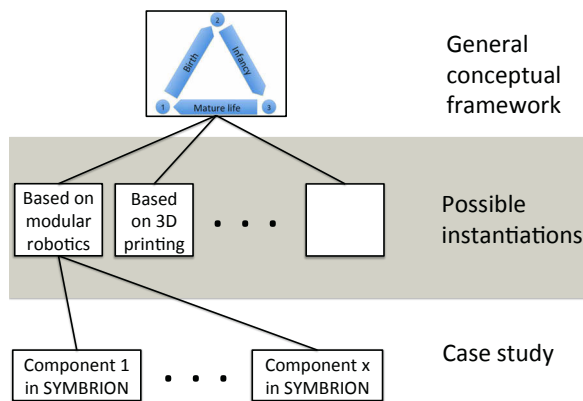

Figure 1: Positioning the Triangle of Life, its possible instantiations in general, and the specific examples used in this paper.

From an evolutionary perspective the framework we advocate here corresponds to a major transition from evolutionary computing (i.e., artificial evolution in software) to Embodied Artificial Evolution (i.e., artificial evolution in hardware) as introduced in Eiben et al. (2012). The roadmap outlined there considers embodiment in the broad sense, including biochemical approaches and treats mechatronics based embodied evolution as one of the possible incarnations. The work presented here represents the first detailed elaboration entirely devoted to that kind of systems.

Finally, the vision behind this paper can also be considered from the perspective of robotics. The relevant subarea here is evolutionary robotics that has a large body of related work, e.g., Nolfi and Floreano (2000); Wang et al. (2006); Trianni (2008). However, most existing systems in this field are based on simulations and use evolutionary algorithms as optimizers in an off-line fashion, during design time. Furthermore, evolution is usually applied to optimize/design some parts of the robot morphology or the controller, but rarely both of them. In contrast, our vision concerns real hardware, on-line evolution during run time, and it includes the evolution of both the morphologies and the controllers. In the system we envision, new robots are produced continuously only limited by the availability of the raw materials and the capacity of the ‘birth’ mechanism. In the resulting system evolution is not a simple optimizer of some robot features, but a force of continuous and pervasive adaptation.

In the landmark Golem project Lipson and Pollack (2000) evolved robots capable of moving themselves across a flat surface; robots were evolved in simulation and the fittest individuals then fabricated by first 3D printing the structural components then adding motors to actuate the robot. Although a remarkable achievement, the artificial creatures evolved then physically realized contained neither sens-

ing nor controller, so were not self-contained autonomous robots. Only the robot’s physical morphology was evolved.

The use of Lego has featured in evolutionary robot hardware. Although not evolving complete Lego robots work has been described, and indeed attempted to formalise the use of Lego structures for evolution. For example Funes and Pollack (1997) describe the simulated evolution, then construction using Lego, of physical bridge-like structures. Peysakhov et al. (2000) present a graph grammar for representing and evolving Lego assemblies, and Devert et al. (2006) describe BlindBuilder, an encoding scheme for evolving Lego-like structures.

Notably Lund (2003) describes the “Building Brains and Bodies approach” and demonstrates the co-evolution of a Lego robot body and its controller in which the evolved robot is physically constructed and tested. Here simulated evolution explores a robot body space with 3 different wheel types, 25 possible wheel positions and 11 sensor positions. Lund observes that although the body search space is small, with 825 possible solutions, the search space is actually much larger when taking into account the co-evolved controller parameters. This work is significant because it is, to the best of our knowledge, the only example to date of the simulated co-evolution, then physical realisation, of body morphology and controller for a complete autonomous mobile robot.

Work by Zykov et al. (2007) describes an evolving modular robotic system on the Molecube platform. In this work, self-reproduction is not a necessary prerequisite of evolution, but rather its target. In particular, the authors evolve self-replicators by employing a genetic algorithm (in a 2D simulation) where the measured amount of self-replication is used as an explicit fitness criterion to evaluate morphologies. Then, in a second stage they evolve a command sequence, i.e., controller, that enables a given morphology to produce an identical copy of itself. However, as yet, there is still no work that has fully demonstrated the online evolution of both structure and function of a modular robotic system, that is fully embodied in the modules themselves.

A related area with practical relevance to our vision is that of self-organizing robotic systems, Murata and Kurokawa (2012). Modular self-reconfigurable robot systems, cf. Yim et al. (2007), are particularly interesting because they constitute one of the possible technologies for implementing the Triangle of Life as shown in Figure 1. However, conceptually such systems are quite different from ours, because the emphasis is on self-reconfiguring morphologies to adapt to dynamic environments, whereas in our evolutionary system, new morphologies appear through ‘birth’ and adaptation of morphologies takes place over generations.

## The Triangle of Life

Throughout this paper we will not attempt to (re)define what life is. Instead, we take a pragmatic approach and con-

sider three features that are typically attributed to life or life-like systems: self-reproduction that relies on heredity, self-repair, and learning.

The proverbial Cycle of Life revolves around birth. We adopt this stance and define the Triangle of Life as shown in Figure 2.

Figure 2: The Triangle of Life. The pivotal moments that span the triangle are: 1) Conception: A new genome is activated, construction of a new organism starts. 2) Delivery: Construction of the new organism is completed. 3) Fertility: The organism becomes ready to conceive offspring.

This concept of the Triangle is generic, the only significant assumption we maintain is the genotype-phenotype dichotomy. That is, we presume that the robotic organisms as observed ‘in the wild’ are the phenotypes encoded by their genotypes. In other words, any robotic organism can be seen as the expression of a piece of code that we call the genome. As part of this assumption we postulate that reproduction takes place at the genotypic level. This means that the evolutionary operators mutation and crossover are applied to the genotypes (to the code) and not to the phenotypes (to the robotic organisms). This fundamental assumption not only makes our envisioned systems more life-like, but –perhaps even more importantly– keeps the door open to enhancing the system with developmental abilities.

In the forthcoming subsections we will elaborate on each stage of the Triangle. For the sake of clarity we appeal to the modular robotic approach and explain some details in that setting. However, we emphasize that the Triangle is a generic framework equally applicable to modular and non-modular approaches.

### Birth

A new robotic organism is created first at genotype level and is thus seeded by a new piece of genetic code that is created by mutating or recombining existing pieces of code. Birth is therefore the first stage of life, specified as the interval between the moment of activating a newly created genome (circle 1 in Figure 2) and the moment when the robot organism encoded by this genome is completed (circle 2 in

Figure 2). In technical terms, this is the period when morphogenesis takes place. In principle, it can be implemented in various ways and later on we will illustrate some in detail. Here we suffice to distinguish two main categories, based on explicit vs. implicit representations of the shape of the newborn robot organism. Using an explicit representation, the genome explicitly specifies the shape of the organism and the process of morphogenesis is executed with this shape as target. Morphogenesis has therefore a clear stopping criterion; it is successfully completed when the target shape has been constructed. Using implicit representation the genome does not contain an exact description of the new shape. Rather, the genome can be seen as a set of rules governing the morphogenesis process that could follow different tracks and thus deliver different end shapes depending on the given circumstances and random effects. Note that this notion of implicit representation includes indirect, developmental representations, EvoDevo, ect. and connects our vision with the nascent area of morphogenetic engineering, cf. Doursat et al. (2012).

### Infancy

The second stage in the Triangle of Life starts when the morphogenesis of a new robot organism is completed (circle 2 in Figure 2) and ends when this organism acquires the skills necessary for living in the given world and becomes capable of conceiving offspring (circle 3 in Figure 2). This moment of becoming fertile is less easy to define in general than the other two nodes of the triangle. However, we believe it is useful to distinguish an Infancy period for two reasons. Firstly, the new organism needs some fine tuning. Even though its parents had well matching bodies and minds (i.e., shapes and controllers), recombination and mutation can shuffle the parental genotypes such that the resulting body and mind will not fit well. Not unlike a newborn calf the new organism needs to learn to control its own body. Depending on the given system design this could take place under protected circumstances, under parental supervision or within an artificial ‘nursery’ with a food rich environment, etc. From this perspective, the Infancy interval serves as a grace period that allows the new organism to reach its full potential. Secondly, the new organism needs to prove its viability. System resources are expensive, thus should be allocated to the creation of offspring with an expectedly high quality. Introducing a moment of becoming fertile (after birth) implies that organisms must reach a certain age before they can reproduce. From this perspective, the Infancy period serves as an initial assessment of implicit fitness that helps filter out inferior organisms before they start wasting resources by producing offspring.

The moment of becoming fertile can be specified by any user-defined criterion. This could be as simple as time elapsed after birth, or some measurable performance, for instance, speed (high is good) or amount of energy collected

(large is good) or number of collisions with obstacles (low is good), etc.

### Mature life

The third stage in the Triangle is the period of maturity. It starts when the organism in question becomes fertile (circle 3 in Figure 2) and leads to a new Triangle when this organism conceives a child, i.e., produces a new genome through recombination and/or mutation (circle 1).<sup>2</sup> It should be noted that at this point we switch perspectives: the beginning of a new life marks the beginning of another Triangle belonging to the new organism encoded by the new piece of genome. As for the ‘old’ organism nothing needs to end here. In other words, conceiving a child does not mean the end (death) of this organism, and it is certainly possible that an organism produces multiple offspring during its mature life. This view is motivated by the intuition behind the proverbial Cycle of Life that inspired our Triangle.

Robotic organisms can exhibit several behaviors during the mature period, depending on the given system and the interests of the experimenter. Here we will only consider two that we consider essential to any real world ALife system: reproduction and self-repair. Reproduction is an obvious requirement, but implementing it is challenging. For multi-cellular robotic organisms we see three feasible options:

1. Based on a ‘birth clinic’. After recombining the genomes of two parent organisms, the genome describing the new organism is beamed to a central facility where there are free robot modules. This is the place where the birth process is executed and a child robot is constructed.
2. Based on self-sacrifice. After recombining the genomes of two parent organisms, one of the parents disassembles and the child is built from its modules. Leftover modules become free riders and serve as available raw material. If the number of modules in the parent is not enough, others are recruited from such free riders.
3. Seed-based protocol. This will be discussed later as the one applied in SYMBRION.

Further to reproduction, we consider self-repair as an essential feature here. In simulation based ALife systems the world and its inhabitants can be stable and error-free, where randomness needs to be added deliberately. In the real-world systems we envision this is not the case, real hardware always breaks down. Thus, some form of self-repair is needed for continued operation after the inevitable breakdowns of the robot/organism. The ability to self-repair is linked to the

<sup>2</sup>Strictly speaking, the moment of producing a new genome need not be the same as activating this genome and starting the morphogenesis process, but this is just a formal detail with no real effect on the conceptual framework.

ability of the organism to perform morphogenesis, as it is very likely that some form of reconfiguration is needed in the event of failure.

### Implementing the Triangle of Life

As mentioned in the Introduction, originally the SYMBRION project considered robotic organisms as transient states of the system. An aggregated organism could achieve goals a simple swarm could not (negotiating an obstacle or reaching a power point) and after completion it could dis-aggregate again. However after five years of research and development many of the components that make up the Triangle of Life have been implemented in hardware or are very close to being implemented in the short term. The purpose of this section is to illustrate these achievements together and to indicate the current state of the art towards an integrated ALife system based on the modular robotic organisms concept.

#### Birth: Explicit Encoding for Morphogenesis

Within the Symbion framework a heterogeneous group of mobile robots can operate in *swarm* mode to – for instance – autonomously explore a region, exploiting the spatial distribution of the swarm. However, when required, Symbion robots can self-assemble to form a 3D *organism*. The process of transition from swarm-mode to organism-mode, with an explicit pre-defined (or pre-evolved) body plan, is also self-organising and proceeds as follows. Any individual robot in swarm mode can act as a ‘seed’ robot, initiating morphogenesis. Typically this might be when that robot discovers an environmental feature or hazard that cannot be accessed or overcome by individual swarm-mode robots. Each robot is pre-loaded with a set of body-plans, and the seed robot will select the most appropriate body plan for the current situation. The position of the seed robot in the selected body plan then determines the next robot(s) that need to be recruited by the seed robot, and the face(s) that they will need to dock into. The seed robot then broadcasts message bearing recruitment signals from the selected face(s), using the IR signalling system built into each docking face. That message specifies which of the three Symbion robot types needs to be recruited.

The autonomous docking approach is illustrated in Figure 3. Initially, a seed robot initiates recruitment of other robots. The pre-evolved body plan is then transferred from the seed robot to them, so newly recruited robots then determine their own position in the growing organism. In discovering its position a robot also determines whether or not other robot(s) need to be recruited. In Figure 3 image 2 they do. Robots’ recruitment signals can be detected by other robots within range (150 cm) to provide rough directional information to any robots in range. IR beacon signals are used at short range (15 cm) to guide the approaching robots for precise alignment with the docking face. Upon com-

Figure 3: Morphogenesis in progress. Image 1: Five robots are in swarm mode. Image 2: Self-assembly is in progress. Image 3: The new organism is complete, but in 2D planar form. Image 4: The organism ‘stands up’ to transform to 3D.

Figure 4: Example of a result from embodied morphogenesis using 5 Symbion robots obtained with the Virtual Embryogeny approach (credits: Markus Dauschan). See Dauschan et al. (2011) for details.

pletion of the docking process, robots stop emitting beacon signals. The same process is then repeated until the pre-evolved structure is formed. A behaviour-based approach is adopted for the design of the morphogenesis controller, together with a well-formatted tree structure which explicitly represents the organism body-plan, as described in Liu and Winfield (2012).

In this way robots initially form a 2D planar structure, see Figure 3 image 3. Once the robots in the 2D planar structure have assumed the correct functionality, according to their position in the body plan, the ‘organism’ will lift itself from 2D planar configuration to 3D configuration (as shown in Figure 3 image 4) and, with respect to locomotion, function as a macroscopic whole.

### Birth: Implicit Encoding for Morphogenesis

An alternative to direct encoding is to consider developmental and generative systems (or *implicit* encodings). In

this setup, the information contained in the genome encodes the *process* of construction rather than an explicitly formulated *plan* of construction. While developmental and generative systems have been studied for some time (cf. the works of Bentley and Kumar (1999); Stanley and Miikkulainen (2003); Bongard and Pfeifer (2003)), the very process of morphogenesis starting from a swarm of autonomous units and going towards a full assembled organism raise additional issues, as the actual morphogenesis should be considered as an embodied process: online and decentralized.

In the last five years, several approaches have been investigated in the Symbion project, from theoretical ideas to practical robotic implementations, as shown in Figure 4. These approaches have been explored and tested, either with simulated or real robots, and have investigated the benefits of deterministic vs. stochastic morphogenesis from different perspectives (either bio-inspired or completely artificial). On one side, genetic regulatory networks (GRN) and artificial ontogenic process have been considered (Thenius et al. (2010)). On the other side, cellular automata (CA) have been used to model the developmental process by considering each robot of the organism as a cell with a von Neumann neighbourhood. In both cases, cells would be considered as homogeneous, that is sharing the same evolved update rules, whether this was explicit CA rules, a GRN update network and any other kind of developmental program. However, each cell would then trigger the recruitment of other cells depending on their current (possibly unique) situation, ultimately leading to a full-grown organism having reached a stable final configuration, as explored by Devert et al. (2011).

What makes these approaches particular with respect to the literature is that it is not only necessary to encode the morphogenesis process itself (i.e. the assembling sequence), but it is also mandatory to consider the actual execution of this process (the *embodied* morphogenesis): individual units are indeed facing a possibly challenging coordination tasks, with the possible constraints of satisfying temporal and spatial constraints (e.g. the assembly ordering can be important). Moreover, open-ended evolution of embodied morphogenesis can benefit from a creative process, that is to come up with original morphological solutions to address the challenges in the environment at hand. We devised a set of performance indicators to encompass these various desired properties and these are described below.

*Evolvability* is considered as the ability for the algorithm to produce *viable* shapes during the course of evolution. It is evaluated by counting the number of unique viable shapes out of a predefined number of tries.

*Initial viability* provides an indicator to estimate how difficult it is to bootstrap an evolutionary process. It is computed by considering only random generations of genotypic description for the encoding under scrutiny, and counting the number of shapes that can actually be build (i.e. viable)

out of the total number of shape descriptions generated.

*Self-repair* stands as one of the typical benchmark for morphogenesis and evaluates how a full organism can be successfully reconstructed from a starting condition that may not match the original initial condition (e.g. from the last recruited robot rather than from the original "egg" robot).

Lastly, *controllability* (unsurprisingly) evaluates the efficiency with respect to evolving the construction process to achieve a particular target shape: the faster the evolution, the better the controllability.

### Infancy: Gait Learning

In our vision of Artificial Life based on hardware birth is followed by the stage of infancy. From an evolutionary point of view the proof of viability at the very beginning of this stage does not need any further consideration. If an organism, for example, consumes too much energy, its genome will not spread. Thus, in SYMBRION we concentrate on the objective of an organism learning to control its own body for locomotion. This is because movement increases the chances to spread the genome during the upcoming phase of mature life, independent of the chosen reproduction implementation during the mature phase. Thus, the objective of gait learning is an indirect one. The obvious easy solution of so-called free-riders, which are organisms staying in place and waiting for others to come by, can only exist in a low number in the population from an evolutionary perspective.

Here, gait learning comes with challenge of an unknown body shape. There may have been passed on a genome performing good locomotion from the ancestor but this good performance does not automatically hold for a different body shape. Thus, investigations on gait learning for a modular multi-robot organism –as it is the case in SYMBRION– always start from scratch.

As mentioned above on-line, on-board evolution was chosen in SYMBRION to be the optimization process. This leads to several important consideration and scientific questions. For example, the part of the genome which is responsible for locomotion could use Lamarckism. This means that at the beginning of mature life not the original genome but the genome altered by artificial evolution during gait learning is used for recombination.

The way of achieving shared control is another consideration. Should the controllers of the single modules in the organism be derived from an identical genome ("homogeneous")? Different genomes ("heterogeneous") would ease the creation of division of labor as some cells would be used to push, others to pull. In Waibel et al. (2009) it is stated that a homogeneous genome of team members is better suited when the task requires high level of cooperation.

Another important aspect is the type of controller being used. This strongly depends on the actuators used for locomotion. The three robot platforms which are the modules of

Figure 5: Multi-robot organism consisting of three modules during infancy. Screenshots show attempts of the organism to create locomotion during on-line, on-board evolutionary.

the multi-robot organism in SYMBRION come with several 2D actuators and one 3D actuator. The primary focus has been on the 3D drive. It is implemented as hinges which makes it possible to lift the other modules. Fig. 5 shows an example of the resulting 3D locomotion of an organism. This leads to a snake- or caterpillar-like motion. Three different controller types known for their evolvability were taken into consideration: CPG (central pattern generator), AHHS (artificial homeostatic hormone system, see Stradner et al. (2012)) and GRN (gene regulatory network). The idea is not to limit the population to one solution in the first place but to let evolution decide. The organism will only be controlled by one type during infancy phase, but the better it performs the greater the chance that this type will also be used by its offspring.

The ongoing work in SYMBRION is the implementation and testing (first results are shown in Fig. 5) for experiments to investigate the considerations raised above concerning gait learning for multi-robot organisms.

### Mature Life: Self-Reproduction

Weel et al. (2013) recently described an egg-based system extending the seed-based protocol from the previous section. The idea is that some of the robot modules that are not part of a robot organism act as an egg whose function is to collect and process genomes of robot organisms for reproduc-

tion. An egg is thus a stationary robot module that organisms can fertilize by sending their genome to it. An egg that has been fertilized by a number of organisms selects two of the received genomes for recombination followed by mutation. Then the egg becomes a seed, and initiates the morphogenesis of a new organism using the new genome.

This system has been implemented in a rather simple, fast simulator, RoboRobo<sup>3</sup> and numerous experiments have been conducted to gain insights into the ‘inner logic’ of this system. In particular, three major parameters have been identified: *egg lifetime*, i.e., how long eggs listen for genomes, *seed lifetime*, i.e., how long a fertilized egg (a seed) is allowed to build the organism its genome encodes before aborting, and *organism lifetime*, i.e., how long a fully grown organism lives before it dies. These experiments have disclosed how these parameters interact, in particular regarding their influence on the size of the organism population, the stability of the organism population, and the average size of the organisms.

### Mature Life: Self-Repair

There are many complex steps proposed in this paper: birth, infancy, mature life over a sustained period. All of these complex and potentially error prone steps may well cause, or be inhibited by faults. Hence, throughout the lifetime of the robotic system, it is inevitable that there will be some form of failure within a robot, or within the organism. When such failures occur, the ability of the organism to perform its task, or even survive, is compromised. Failures can be caused by a range of different faults ranging from mechanical failures, to electronic hardware or software faults and as such prevent the organism from performing its task. For continued operation over the full lifetime of the robot/organism some form of self-repair is needed. The ability to self-repair is linked to the ability of the organism to perform morphogenesis, as it is very likely that some form of reconfiguration is needed in the event of failure.

We report here on two approaches of self-repair that have been explored. The first could be considered a type of self-assembly, as reported in Murray et al. (2013) where robots are able to form ad-hoc structures, with no pre-determined shape, as opposed to work described above where a shape is seeded into the robotic unit. Murray et al presented an algorithm that showed successful reconfiguration ability of specifically tailored e-pucks that could form the aforementioned structures.

Further work by the SYMBRION project, as yet unpublished, goes much further to permit a true self-repair approach for organisms. Using techniques developed within the project for the detection Timmis et al. (2010) and diagnosis Bi et al. (2010) of faults, combined with the morphogenesis approach described here, SYMBRION organisms can

perform a partial disassembly then a full reassembly back to the original structure, in a distributed and autonomous manner. Should a robotic unit fail at any position within the organism, the approach permits for the removal of that unit and a reconstruction of the organism using the morphogenesis approach described.

### Concluding Remarks

In this paper we have introduced the Triangle of Life: a conceptual framework for artificial systems in which robots actually reproduce. Our proposed framework contrasts with traditional evolutionary robots approaches in several ways. Firstly, the life cycle does not run from birth to death, but from conception (being conceived) to conception (conceiving one or more children). Secondly we envision the whole process taking place in real time, with real robots in the real world. We do not prescribe how the process should be implemented, but two contrasting approaches present themselves: one in which some infrastructure provides materials and processes for robot birth, and another infrastructure-less approach which could be thought of as an extension to modular self-assembling robotics. The third departure from conventional practice is that fitness is tested primarily through survival to maturity and successful mating, rather than against an explicit fitness function. Thus a large number of factors including individual health and development, the living environment (which may include multiple generations of conspecifics), and simple contingency will influence whether an individual survives to pass on its genetic material. Importantly it follows that selection is also implicit. Although we are describing an artificial life system, the process of selection is much closer to Darwinian natural selection.

Finally we should speculate on how such an artificial life system might be used. Two contrasting applications present themselves. One as an engineering solution to a requirement for multiple robots in extreme unknown or dynamic environments in which the robots cannot be specified beforehand: robots required to explore and mine asteroids, for instance. The other application is scientific. Our proposed artificial life system could be used to investigate novel evolutionary processes, not so much to model biological evolution – life as it is, but instead to study life as it could be.

### Acknowledgements

The authors gratefully acknowledge the contributions of all SYMBRION partners. In particular, we are indebted to Markus Dauschan, Evert Haasdijk, Serge Kernbach, Wenguo Liu, Jean-Marc Montanier, Jessica Meyer, Lachlan Murray, Marc Schoenauer, Michele Sebag, and Berend Weel.

### Introduction

Biochemical reactions in living organism usually take place inside cells. The characteristic feature of these reactions is their executability; the organism does not produce certain substances all the time, but only when they are needed. The reaction is usually triggered after receiving an extra- (or intra-) cellular signal. Stimuli-responsiveness is mostly possible because of compartmentalization of the cells. Reactants, enzymes and other factors are separated to different parts of cells by membranes forming organelles. Upon receiving a signal, the substances are selectively transported through the membranes and a reaction occurs.

In order to mimic that behaviour we present internally-structured cell-like micro-particles with a diameter around 50  $\mu\text{m}$ . The particles are formed by an alginate gel, thermo-responsive liposomes form internal compartments filled by an encapsulated content. The particles also contain ferrofluid ( $\text{Fe}_2\text{O}_3$  magnetic nanoparticles). High-frequency magnetic field causes heating of the particles hence release the content from thermo-sensitive liposomes into the gel body and then out of the particles (Hanuš, et al. 2013). Thermo-sensitive liposomes are characteristic by a change of bilayer structure at certain temperature.

Figure 1: Scheme of the particle and principle of triggering the reaction. The substrate is released from liposomes after induction heating of particles and it is oxidized in the gel by means of the immobilized enzyme.

Utilizing these particles we studied an enzymatic oxidation of ABTS (2,2'-azino-bis(3-ethylbenzothiazoline-6-sulphonic

acid)) catalyzed by the enzyme laccase. The substrate was encapsulated inside the liposomes and the enzyme was immobilized into the alginate hydrogel. A scheme of the particle and the principle of reaction triggering is shown in Figure 1.

### Preparation

Liposomes were made from DPPC (1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine) and cholesterol at a molar ratio of 8:1 (DPPC:cholesterol). They were prepared by the hydration method followed by an extrusion through 100 nm polycarbonate membrane. Magnetic nanoparticles were made by the precipitation of  $\text{FeCl}_2$  and  $\text{FeCl}_3$  in an ammonia solution. A mixture of the ferrofluid, liposomes with ABTS, laccase and sodium alginate was dripped into a solution of copper(II) sulphate by a syringe with a needle in order to produce 1-2mm particles (Ullrich, et al. 2013) or by an ink-jet print-head in the case of micro-particles ( $\sim 80 \mu\text{m}$ ) (Haufová, et al. 2012). Microscopic image of such micro-particles is in Figure 2. After 1 hour of cross-linking, the particles were washed with water and then transferred to 10 mM acetate buffer (pH = 5.0). The product of the enzymatic reaction is intensively coloured; this enables spectroscopic detection at 415 nm.

Figure 2: Microscopic image of ink-jetted micro-particles containing iron oxide nanoparticles, laccase and liposomes enclosing solution of ABTS.

## Results

At first, laccase was immobilized within calcium alginate gel. A significant decrease of the enzyme activity was observed. Leakage of the enzyme during cross-linking and the presence of calcium ions was found to have the main effect on the enzyme deactivation. After 1 hour of gel cross-linking, about half of the original amount of laccase leaked out of the beads. Moreover, the activity of laccase in 150 mM  $\text{CaCl}_2$  was about 10-times lower than in 100 mM acetate buffer. On the other hand, the enzymatic reaction was found to be slightly faster in 150 mM copper(II) sulphate compared to the buffer. That led us to use copper sulphate solution for cross-linking instead of calcium chloride that was used originally for the preparation.

The temperature-dependent release rate of the product has been investigated. At first, millimetre-sized particles were studied. It was found that approximately 10 % of the substrate was released at room temperature ( $\sim 23^\circ\text{C}$ ) in 3 hours, but the leakage could be decreased to 1 % by storage in a refrigerator. On the other hand, only 5 minutes in a  $50^\circ\text{C}$  water bath was enough to release and oxidize almost all of the encapsulated substrate.

Similar experiment was carried out with iron-oxide nanoparticles and RF-heating by an induction coil (frequency 400 kHz, max. amplitude 20 mT  $\sim 100\%$  in Figure 3). The effect of the magnetic field intensity and duration of the RF-pulse were studied. Precise control of the magnetic field led to a step-wise release hence dosage control of the product. Functionality of this principle was then verified on micrometre-sized particles prepared by the ink-jet printing (Figure 3).

Figure 3: Release of the reaction product from alginate micro-particles. Legend: (♦)(■) samples heated by an induction coil; (●) not-heated reference sample; (- -) intensity of RF-heating. Relative absorbance 100% refers to an absorbance after release all the product.

## Conclusions

Artificial cell-like particles have been created. Liposomes have a function of inner compartments and an alginate gel forms an artificial protoplasm. The particles contain also iron oxide nanoparticles enabling a control of processes inside by a temperature change. Utilizing this system we demonstrated the

ability to control the rate of reaction-diffusion processes remotely by a RF-field. Micro-particles containing thermo-sensitive liposomes, holding the substrate for enzymatic reaction (ABTS), and an immobilized enzyme (laccase) released a significant amount of the reaction product after an exposure to a RF-magnetic field. This opens up the possibility to use such particles as micrometre-scaled bioreactors for more complex reaction networks using liposomes with different composition hence a different bilayer transition temperature. Also local, on-demand synthesis and release of pharmacologically or otherwise active compounds with a short lifetime could be possible.

Keywords: inorganic biology; 3d printers; artificial life; inorganic chemical cells (iCHELLs); 3d printer-based liquid handling robots; flow-bots

In our laboratory we have been developing new approaches to discover the 'transition-to-evolvability' in chemistry. This is because if we can discover or engineer an abiotic system that can evolve (we could define this as an inorganic chemical cell –iCHELL, see Figure)[1] we might be able to suggest that synthetic biology can exist in many chemical forms, of which the terrestrial biology found on planet earth is one subset. It could even help us establish the idea that evolvability is the key signature that defines living from non-living systems. In this contribution I will describe how we are connecting evolutionary algorithms, hardware (e.g. flow systems [2], 3d printers[3] and liquid handling robots) and complex chemical systems to produce new types system without classically defined biological genetic material, yet with the potential to evolve.

## Abstract

Evolutionary robotics has been successful in creating agents that successfully link perception with appropriate action. However, the visual fields utilized by such agents is usually extremely small compared to the retinas linked to the visual cortex of animals. Evolving a cortex that processes larger fields of view in a selective and robust manner is challenging because fitness landscapes that are sensitive to this level of details are difficult to design. Here, we decouple the perception from the action part of evolutionary robotics, and present a new way to evolve logic circuits to perform image recognition on the well-known MNIST data set, which comprises 60,000 training and 10,000 testing handwritten numerals. The logic circuits are encoded in a genome that is evolved using a fitness function based on the true positive and true negative classification rates of the numerals. Following evolution, individual circuits achieve in excess of 80% recognition accuracy on the testing data. By pooling highly evolved individual circuits from multiple evolutionary histories into a committee, testing accuracy is increased to 93.5%.

This work demonstrates that evolving logic circuits to solve a classification task is feasible. We also found the evolved circuits to be much smaller in scale compared to other machine learning methods that are conventionally used on such problems. To our knowledge, this represents the first time that relatively small logic circuits have been evolved to reach this level of performance on the automated recognition of handwriting, and promises new approaches to the integration of evolutionary algorithms and intelligent systems.

## Introduction

The primary visual cortex of mammals is a marvel of complexity and function, and has been studied for decades both by those wishing to *understand* it, as well as those wishing to *duplicate* it. Object recognition by the visual cortex is fast (Thorpe et al., 1996), specific, and invariant: we can recognize faces, for example, in different orientations, under a variety of lighting conditions, and bearing different expressions. Significant efforts have been expended on modeling the hierarchical organization of the visual cortex, with the aim of both elucidating the algorithm behind fast and invariant object recognition (Riesenhuber and Poggio, 1999), as well as harnessing it for computer vision (Serre et al., 2007).

The usefulness of such a system for the organism bearing it is almost too obvious to point out: it is clear that the selective advantage of a fast, accurate, and robust sensing system must be enormous. Indeed, the visual cortex evolved to be the largest system in the human brain.

While significant progress has been made on our understanding of the visual cortex, the development of a visual cortex suitable for embodied robotics (Pfeifer and Bongard, 2006) remains a challenging problem. Typically, embodied mobile robots need to carry lightweight, fast, and energy-efficient components, and typically such systems have a very limited bandwidth. Most (if not all) of the implementations of automatic computer vision fall short in one or more of these requirements. To be sure, advanced systems such as Google's self-driving car (Ibañez-Guzmán et al., 2012) have achieved extremely robust object recognition and navigation skills, however at the cost of processing almost a Gigabyte/s of sensorial data (Chau et al., 2013). Less advanced systems (such as, say, an ant) navigate robustly with arguably nine orders of magnitude less sensorial data, using a far more compact circuitry, and minimal energy requirements. How can we understand the structure and function of such visual systems?

## Evolutionary robotics

Within the field of evolutionary robotics (Nolfi and Floreano, 2000; Floreano and Keller, 2010), it is becoming more and more clear that algorithms for perception should not be separated from those for action, that instead perception and action should be considered as an integrated system computing appropriate behavior from contextual information. Evolving the neural control structures for navigation (Floreano and Mondada, 1998; Edlund et al., 2011) has the advantage that it is free of any preconceived notions of what is designable and the added bonus of robustness, because the prime directive of an evolutionary fitness landscape is the survival of the agent. Advances have been made specifically in the area of *active categorical perception*, where an agent actively moves to better categorize the object it sees (Beer, 1996, 2003; van Dartel et al., 2005; Marstaller et al., 2013).

In this type of work, the visual system of the agent is necessarily primitive, as the emphasis lies squarely on the evolution of the perception-action loop. One approach to extend this work could be to simply extend the size of an agent's retina, with the hope that the added detail within the visual field will prove useful for robot behavior. The drawback of this approach is familiar to most that have worked in this field: designing a fitness landscape (Nelson et al., 2009) that makes exquisitely accurate and robust image recognition necessary is extremely challenging, because in most artificial worlds an agent can achieve success with relatively few cues. Floreano et al. (2005) were able to evolve robots that navigate using an evolved retina with a resolution of  $5 \times 5$  visual neurons, and showed that selection tried to exploit a subset of salient visual features, rather than to process the whole available image.

In order to test whether image recognition algorithms can be evolved in the absence of actions—and to circumvent the problem of having to design a fitness landscape where fast, robust and selective image recognition is necessary for appropriate behavior—we decided to study whether evolution can re-create an object-recognition system suitable for embodied robotics, by evolving an artificial visual cortex that recognizes hand-written numerals. This task (a sub-problem of what is commonly referred to as “optical character recognition”, or OCR) is a well-known staple of the machine learning community, and as a consequence several benchmarks are available to compare performance. In our work (as opposed to the standard machine learning application), we have more goals besides trying to achieve maximum accuracy in image classification. We also require the resulting network to be fast, small, and easily transferrable from one computing platform to another. But most importantly, the solution must be evolvable. We can imagine, for example, that the evolved visual cortex would be connected to the neural controlling machinery of an embodied robot, so that both can then evolve together.

In what follows, we use evolutionary algorithms to evolve logic circuits that classify the numerals from the MNIST data set (LeCun et al., 1998), a well-known benchmark in OCR. Evolutionary algorithms employ the principles of evolution by natural selection in a computational context to solve complex problems (Bäck, 1996). Our approach makes use of a framework to evolve *Markov networks* (MN), a development from recent work (Edlund et al., 2011). MNs comprise a series of state variables that interact with one another through a collection of evolved “computational gates.” These gates specify how state variables change in response to one another. Gates can be either probabilistic, much like fuzzy logic, or deterministic, as in traditional logic circuits. The Markov networks themselves are represented by a circular list of integers (the “genome”) that describes each gate and the state variables with which they interact. Mutations within our evolutionary algorithm operate directly on these

genomes, and we employ a fitness function that is based on true positive and true negative recognition rates. In this work, we make use of deterministic gates only, and thus evolve logic circuits that are essentially complex boolean functions that classify numerals from the MNIST data set.

Previous techniques applied to OCR on handwritten characters include K-nearest-neighbors (LeCun et al., 1998), support vector machines (Decoste and Schölkopf, 2002), and learning classifiers such as artificial neural nets and convolutional nets (LeCun et al., 1998; Ciresan et al., 2012; Salakhutdinov and Hinton, 2007). In the case of neural network-based approaches, edge weights are typically optimized based on an error-minimization algorithm such as backpropagation. However, the number of network layers, along with the number of computational units per layer, remains fixed during training. Over time, these approaches have improved in performance on the MNIST data set. For example, in 1998 the best neural network *error rate*, the rate of misclassification on the test images, was 1.6%, achieved using a 2-layer neural network with 300 hidden states (LeCun et al., 1998). In 2007, Salakhutdinov and Hinton achieved an error rate of 1.0%, using a “deep learning” neural network architecture (Salakhutdinov and Hinton, 2007). Deep learning involves the use of a higher-than-normal number of layers; in this case, five neural network layers were used, with all but the last layer using hundreds of nodes. In 2010, Ciresan *et al.* were able to decrease the error rate to 0.35%, using six layers and an even greater number of nodes per layer (Ciresan et al., 2010). The current world record error rate for the MNIST data set is 0.23%, again set by Ciresan *et al.* in 2012, where they used a 35-member committee (7,700 total neurons) of convolutional networks trained via back-propagation for 490 hours on GPU (Ciresan et al., 2012).

Here we use evolution to discover logic circuits that classify the numerals from the MNIST data set. The evolved circuits are of larger scale than other evolutionary approaches, having 784 inputs and 20 outputs, and unlike ANNs and convolutional networks, evolve to a highly concise representation of about 100 computational gates. While individual evolved logic circuits have remarkable accuracy given their relatively small size, the diversity inherent to evolutionary algorithms enables us to make effective use of *committees*. Using committees of 30 circuits, we achieve an accuracy of approximately 93.5% on the MNIST data set. This level of scalability of logic circuit evolution has not been seen in other studies (Stomeo et al., 2005; Vassilev and Miller, 2000; Torresen, 2001), and demonstrates that the evolution of large logic circuits to perform a practical application is feasible. Finally, because Markov networks represent logic circuits, they are capable of being rendered on physical hardware such as FPGAs.

Figure 1: A schematic showing how a Markov network operates. Inputs (green) in a 4x4 image field connect to logic gates (red), which produce the 10 outputs (blue).

## Methods

### Evolving logic circuits

Defined as a set of probabilistically interacting state variables (Koller and Friedman, 2009), Markov networks (MNs)—which are frequently used to model stochastic processes—can also encode a wide variety of behaviors. The state variables (SVs) represent inputs to the MN, outputs from the MN, and “hidden state variables,” that is, SVs that are internal to the MN. A proof-of-principle that MNs can successfully evolved to control behavior (including the usage of memory) was provided in a study of animat navigation in a maze (Edlund et al., 2011). There, some SVs act as sensors of the external environment, and other SVs act as motor outputs and memory. To evolve logic circuits, we use that framework for the evolution of MNs, however, here we use only deterministic gates, as we will discuss in more detail below. Figure 1 depicts an example Markov network. Here, inputs to the MN are pixels from a small 4x4 image (green). These inputs are provided to a series of logic gates (red), which in turn produce outputs (blue).

State variables are connected to each other in a directed fashion in a MN, and this connection is mediated through logic gates. Each gate is connected to a number of SVs as input and produces a specified number of SVs as output. During each network update, the inputs to each gate are used to calculate the values that will be written into the gate’s output SVs. The outputs produced by a gate thus depend on the value of the input SVs and the specific logic of the gate. To illustrate how these gates work, Table 1 shows a truth table for a 2-input, 2-output logic gate. Here, this gate is connected to input SVs  $a$  and  $b$  and output SVs  $c$  and  $d$ . If  $a$  and  $b$  take the binary values 1 and 0 respectively during one *tick* (a tick represents one execution of all logic gates in a MN), then this gate will write a 1 into both output SVs  $c$  and  $d$ . If more than one gate writes into the same SV, the values are combined via a logical OR.

To evolve logic circuits, we encode the circuit within a digital genome: a circular list of integers. Within this genome, each gate is encoded by a gene. The beginning

Table 1: A sample logic table for a deterministic gate with 2 inputs and 2 outputs.

| Inputs |     | Outputs |     |
|--------|-----|---------|-----|
| $a$    | $b$ | $c$     | $d$ |
| 1      | 1   | 0       | 1   |
| 0      | 1   | 0       | 0   |
| 1      | 0   | 1       | 1   |
| 0      | 0   | 0       | 1   |

of each gene is identified by a specific marker (the “start codon”), and the gene defines the entire functionality of its associated gate. Specifically, genes specify the identity of input and output state variables for each gate, as well as the logic table defining the operation of the gate. In this study, the genome is limited to 40,000 integers, which has an overall capacity of a few thousand genes.

In the evolutionary process, the genome is subject to point mutation, duplication, or deletion. A *point mutation* in the genome randomly changes the value of an integer to another value, whereas a *duplication* or *deletion* inserts random integers into or removes a small section from the genome, respectively. Aside from selecting the range from which random integers are drawn, there are no constraints placed on the values of the integers within the genome. For this reason, not all genes will necessarily be useful toward the problem at hand. Of course, as with natural genomes, nonfunctional genes can serve as a “bank” of genetic diversity that evolution can make use of. Finally, while the MN framework allows the input and output dimension of gates to change via mutation, for simplicity here we fix gates to 4 inputs and 4 outputs. A detailed exposition of the encoding of gates within the circular list of integers is provided in the supplementary information of Edlund et al. (2011).

### Recognizing characters

Each image in the MNIST data set is rendered as a  $28 \times 28$  pixel grayscale image, where each pixel has a grayscale value from 0 to 255. A sample of these images is shown in Fig. 2, along with a sample of difficult to classify images on the right. In the literature, numerous pre-processing steps are often taken in order to render the images more conducive to particular machine-learning methods, but here we use a simple binary transform on the raw images as delivered in a previous study (LeCun et al., 1998). Specifically, we transform each image such that all pixels with a gray level of 0 are treated as a binary “0,” and all nonzero pixels are treated as a binary “1.” Each of the 784 binary pixel values are then provided to MNs as inputs. Each MN produces 20 outputs, which represent the classification produced by the MN. Each pair of output bits represents a yes/no answer for one class. Specifically,  $c_i = b_{0,i} \wedge \neg b_{1,i}$ , where  $b_{0,i}$  is the first bit for class  $i$ ,  $b_{1,i}$  is the second bit for class  $i$ , and

Figure 2: A sample of grey-scale images of hand-written numerals from the MNIST database (left), along with a set of difficult to classify images from the same set.

$c_i$  is the MNs boolean decision for whether the image under consideration is thought to belong to class  $i$ .  $b_{0,i}$  can be thought of as the activating bit for a class decision, whereas  $b_{1,i}$  serves an inhibitory function such that it negates a positive class decision by  $b_{0,i}$ . We allow the MNs to produce multiple answers for each image. This may seem counter-intuitive, but with the appropriate choice of fitness function, the MNs can evolve to only guess the correct answer, while producing negative answers for the other classes.

The fitness function used to evolve MNs is based on the true positive and true negative rates (TPR and TNR, respectively) of a network's decisions for each class. In essence, a network is rewarded for identifying which class an image belonged to, and also for identifying which classes it did *not* belong to. If even one of these details was correct, the network receives some fitness for that guess. By allowing such "partial credit," we provide a more smooth fitness landscape than if the exact answers for an image were to be required. The specific fitness function we use is:

$$f = \sqrt{\sum_{i=0}^9 (\text{tpr}_i + \text{tnr}_i + \text{out}_i)^2}, \quad (1)$$

where  $\text{tpr}_i$  is the measured true positive rate on class  $i$ ,  $\text{tnr}_i$  is the true negative rate on class  $i$ , and  $f$  is the resulting fitness. If the network outputs a positive decision for *any* image of class  $i$ ,  $\text{out}_i$  is set to 1.0, thus encouraging the networks to evolve to classify *all* numerals (as opposed to simply focusing on the more easily classified numerals). Ties (outputting multiple classifications for a single image), are broken randomly to produce an accuracy score. We did not use the accuracy score of the network as fitness, as the resulting landscape proved too difficult to adapt to (data not shown). Note that when reporting fitness, we show the percentage of the maximum fitness achievable via Eq. (1).

The MNIST data set is divided into two parts: A set of 60,000 training images, and a set of 10,000 testing images. The Markov networks were only evolved on the training images. After evolution on the training set, the most fit individual network was then tested on the testing set. The accuracy

Figure 3: Mean training fitness and test accuracy of dominant individuals over time, over 30 independent runs. Using 200-fold bootstrapping, (small) error bars are constructed depicting 95% confidence intervals around the mean.

score of this individual was calculated as the fraction of test images correctly identified by the circuit. The parameters of our evolutionary algorithm are summarized in Table 2. In all, 30 replicate populations were evolved on the training set. After every 25,000 updates (up to 250,000 updates), we tested the highest-fitness individual from each replicate and recorded its accuracy.

Table 2: Parameters for the evolutionary runs.

| Parameter                        | Value   |
|----------------------------------|---------|
| Updates                          | 250,000 |
| Population size                  | 500     |
| Starting gates                   | 100     |
| Max inputs                       | 784     |
| Max outputs                      | 20      |
| Inputs per gate                  | 4       |
| Outputs per gate                 | 4       |
| Gene duplication rate per update | 0.05    |
| Gene deletion rate per update    | 0.05    |
| Site mutation rate per update    | 0.001   |

## Results

Figure 3 shows the mean training fitness and testing accuracy of the dominant (most fit) individuals from 30 different replicates over time. Fitness and accuracy rise to approximately 96% and 79% over 250,000 updates, respectively. The single best individual accuracy (across the 30 replicate runs) is 81%. High fitness is indicative of high accuracy, although the fitnesses of the individuals are much closer to maximum than their accuracies. The two measures are also strongly correlated. Figure 4(a) demonstrates this in a scatter plot of the relationship between training fitness and training accuracy over time ( $\rho = 0.9255$ ). The correlation is not perfect, however, because our fitness function did not reward

Figure 4: (a): Relationship between training fitness and training accuracy of the 30 replicates over time ( $\rho = 0.9255$ ). Note that training fitness reaches much closer to its maximum than training accuracy. (b): Relationship between training accuracy and testing accuracy of the 30 replicates over time ( $\rho = 0.9757$ ). The  $y=x$  line is shown for clarity, and shows how most of the time training accuracy is higher than testing accuracy, although there are many cases where the reverse is true.

accuracy *per se*, but rather the true positive and true negative rates of the Markov network class decisions. Similarly, as the data in Figure 4(b) shows, accuracy on the training set correlates well with accuracy on the testing set ( $\rho = 0.9757$ ). While training accuracy is often higher than testing accuracy, it can also be lower, and the two accuracies are never different by more than a slight amount. Using the same reasoning as with Figure 4(a), one can say that the discrepancy between training and testing accuracies is due to the fact that the networks were not specifically evolved using accuracy as a fitness function. The results also demonstrate that the networks were capable of generalizing features learned from the training set to the images of the testing set.

Figure 5: The structure of the Markov network from 250,000 updates with the highest individual testing accuracy. The green squares are the inputs corresponding to the pixels of the 28x28 image field. The red squares are the gates. The blue squares are the output nodes, ordered from  $\{b_{0,0}, b_{1,0} \dots b_{0,9}, b_{1,9}\}$ .

An example evolved Markov network is depicted in Figure 5, with the inputs shown according to their location on the 28x28 image field. The network shown is the individual at 250,000 updates that has the highest testing accuracy, (81.16%). Notably, the network is able to achieve a high relative testing accuracy with a sparse number of inputs. Because of the diversity of the evolutionary process, the structures of the Markov networks that evolved were not all the same as in Figure 5. However, common features of the networks tended to appear. Figure 6(b-d) shows the probabilities of pixels from the 28x28 image field being used as inputs by the 30 dominant individual networks from the replicates at 25,000, 100,000, and 250,000 updates, respectively. The colors range from dark blue to dark red, with a dark blue pixel meaning that no networks had an input at that location, and a dark red pixel meaning that all 30 networks had an input there. It is clear from this progression that certain areas of the image field are favored by the networks more than others. This demonstrates how the Markov networks improve their fitness over time by focusing on certain areas of the image field, and clearly shows the sparsity of the inputs to the networks.

In addition, the entropy of the pixels of the 60,000 training images is shown in Figure 6(a), with dark blue representing zero bits of entropy and dark red representing the max of

Figure 6: (a): Training image entropy per pixel Eq. (2). Dark blue represents zero bits of entropy and dark red represents the maximum entropy of 1 bit (see colorbar) (b-c): Network input probabilities at 25,000, 100,000, and 250,000 updates, respectively. Colors follow the colorbar.

1 bit. Entropy was calculated in order to compare it to the input probabilities of the networks. Entropy of each of the pixels was calculated using the probability  $p_i$  that a pixel  $i$  was a binary 1 (“turned on”) over all images:

$$H(x) = - \sum_{i=1}^{784} p_i * \log_2(p_i), \quad (2)$$

where  $\text{pixel}_i$  is the probability that a pixel in the set of training images is represented. As shown in Equation 2, entropy of a pixel is higher the closer its probability of being turned on is to 50%. If a pixel was turned on either none or all of the time, its entropy was zero. It was hypothesized that pixels with higher entropy would be more informative about the data set in general, and thus the networks would preferentially connect to these high-entropy pixels. When comparing Figure 6(a) to Figure 6(b-d), this indeed appears to be the case, especially on the border areas.

While the Markov networks focus on certain areas of the image field for input, Figure 6(b-d) also shows how the mean number of inputs of the networks increases over time. Figure 7 depicts a curve showing the mean number of inputs of the networks over time, along with the mean number of gates. Both the mean number of inputs and number of gates increases over time, although after approximately 75,000 updates the increase of both values occurs at a lower rate. Note that because gates can share inputs, there is not a simple linear relationship between the number of gates and the number of inputs. The mean number of outputs per gate also tends to increase, as depicted in Figure 8 (the number of inputs per gate is almost always 4 and is not shown here). It is not a requirement of Markov networks for there to be this concomitant increase in the number of outputs per gate alongside an

Figure 7: Mean number of inputs (neurons that connect to image pixels) averaged over 30 independent runs (blue, triangles) and mean number of logic gates (red, circles), as a function of evolutionary time. Error bars are constructed using 200-fold bootstrapping with 95% confidence intervals.

increase in the number of inputs and gates. Therefore, this phenomenon in the evolution of the networks suggests that one of the ways that the networks get better at recognizing the images is by having the gates increase the number of outputs that they cover as opposed to focusing on only one output.

Following the evolution of individual Markov networks, we next constructed committees from the dominant individuals from all 30 replicates. A committee is a method for combining the answers of multiple individuals to improve performance, a technique that has been shown to be effective on the MNIST data set (Ciresan et al., 2012). The committee decisions were formed by summing the decisions from each individual. Interestingly, committee results were strongest when individual decisions were allowed to contain votes for multiple classes, i.e., individual votes were allowed to contain ties. At the committee level, the single classification

Figure 8: Mean number of outgoing edges per logic gate as a function of evolutionary time. Error bars are constructed using 200-fold bootstrapping with 95% confidence intervals.

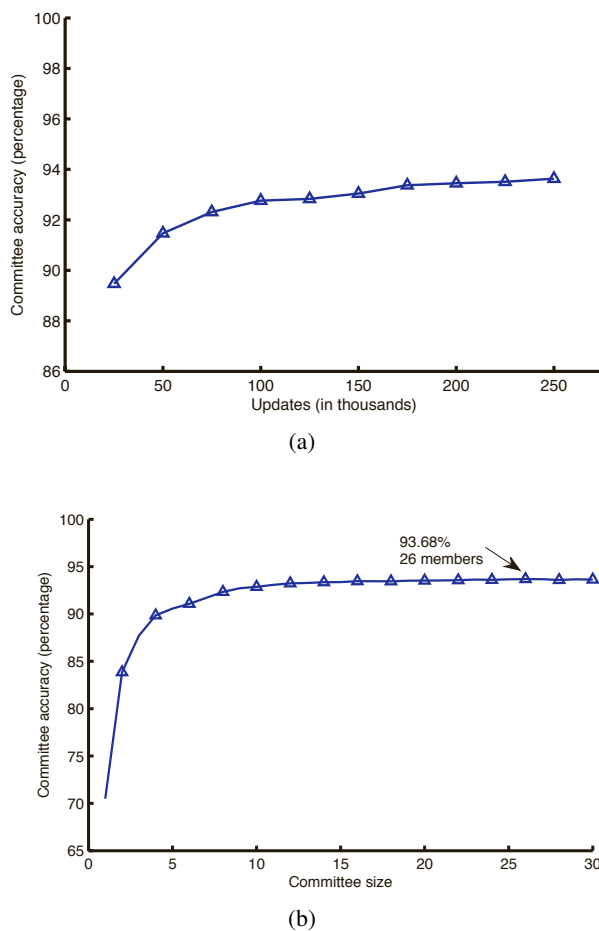

Figure 9: (a): Accuracy of a 30-member committee over evolutionary time. (b): Committee accuracy as a function of committee size, showing diminishing returns. The arrow indicates the most accurate committee.

with the most votes was selected, and ties were again broken randomly. Figure 9(a) shows the 30-member committee accuracy over time on the testing set. The accuracy gradually increases, reaching 93.63% after 250,000 updates.

To examine the effects of committee size on accuracy on the test set, the most-fit individuals from each of the 30 replicates at 250,000 updates were ranked according to how well they did on the training set in terms of fitness, and the highest-ranked  $n$  members assigned to a committee of size  $n$ . We can then determine the dependence of committee accuracy as a function of committee size. Figure 9(b) shows that committee accuracy dramatically increases as committee members are added. We note that a committee of 30 members does not provide the absolute best accuracy for this update (93.63%), although it is very close to the maximum committee accuracy achieved (93.68% with 26 members). These results clearly show the utility of increasing the size of a committee. Although the benefit from adding

new committee members faces diminishing returns, it is remarkable how only a few committee members can dramatically improve accuracy. This suggests that the diversity of the evolutionary process can produce Markov networks that are able to recognize different aspects of the OCR problem, such that pooling their answers in a committee plays on their strengths.

## Conclusion

We have demonstrated an evolutionary approach to image classification that is capable of high accuracy on the MNIST benchmark, while having a small computational footprint. Because the network is essentially a digital circuit, it is easily transferred from one computational environment to another, for example, we have used it on a standard tablet computer to recognize digits drawn by the user on the screen. While the accuracy is probably sufficient for usage in mobile agent navigation, we believe that the image recognition accuracy can be improved significantly. For example, we have only explored a limited set of parameters and fitness functions, and a number of unexplored avenues to improve accuracy remain. For example, there undoubtedly exists a fitness function that shows a better correlation with accuracy than the one used here. Also, pre-processing images to extract salient features (such as lines and corners) could reduce the dependence of class assignments on the locations of specific pixels. Increasing the number of images in the training set by modification of the current set could also help. Indeed, the work by Ciresan et al. (2012) utilized both of these methods.

Perhaps the most promising path to more accurate and invariant image recognition, however, is to create an evolutionary landscape and framework where a more hierarchical image processing algorithm can evolve. In this work, we have limited the processing time (from reading the input image to writing the image classification into the outputs) to exactly one time step. As a consequence, the resulting algorithm cannot possibly use any intermediate Markov variables to build up representations Marstaller et al. (2013) of the concepts. In contrast, a complex visual cortex is hierarchical and processes the simple elements of the image into more and more complex “concepts”, which are then finally used to categorize. We have seen in preliminary work that such a hierarchical organization can emerge, but at the price of a significant slowdown in evolution.

## Abstract

Spontaneous evolution of neural cells was recorded around 4-34 days in vitro (DIV) with high-density CMOS micro-electrode array, which enables detailed study of the spatio-temporal activity of cultured neurons. We used the CMOS array to characterize 1) the evolution of activation patterns of each putative neurons, 2) the developmental change in cell-cell interactions, and finally, 3) emergence of multiple timescales for neurons to exchange information with each other. The results revealed not only the topology of the physical connectivity of the neurons but also the functional connectivity of the neurons within different time scales. We finally argued the relationship of the results with “functional networks”, which interact with each other to support multiple cognitive functions in the mature human brain.

## Introduction

How can the gap between living and nonliving matter be bridged? Since 1987 when Artificial Life was launched by Christopher Langton, we have not answered this question. Rodney Brooks wrote in the paper (2001) that there are four possibilities why we still cannot make living machines: 1) An alife model is correct, but several parameters were set incorrectly; (2) an alife model needs more complexity; (3) we need more computational power; and (4) a new fundamental law in addition to the laws of physics is needed. In this paper, we search for the possibility of (2) yet unrevealed laws of neuro-dynamics, by studying cultivated neural cells on a glass plate.

Biological neurons are cultivated on a glass plate from neural “seeds”. The seeds develop into either neural or glia cells. Neurons have cell bodies, axons, and numerous dendrites, which the neurons use to connect with each other. A unique characteristic of the present study is that we record the action potential from neurons by using a CMOS array glass plate. As we will describe later, each CMOS is the same size order of the neurons. Therefore, by using the CMOS array, we can potentially accurately record the time series of each neural firing. A remarkable aspect of this biological neural network is the developmental process. The entire time course of the growing process can be recorded

with the CMOS array. We analyze the time series data to characterize the developmental dynamics.

A disadvantage of this experiment is that we have no way of designating which neurons connect to which. We thus measure the information transfer from the time series to infer the neural connectivity. This method reveals not only the topology of the physical connectivity of the neurons but also the functional connectivity of the neurons within different time scales. A finding in this paper is that growing biological neurons use different time scales to exchange information with each other.

The paper is organized as follows. In section of Materials and Methods, the specifications of the CMOS array and the biological conditions for the neural cells are provided. The method for cultivating cells and associated techniques are also described. In section of Result and Discussion, the analyzed results are presented. The activation patterns of each cell are quantified with inter-spike intervals (ISIs). Cell-cell interaction is also inferred by transfer entropy (TE), which reveals that multiple functional networks emerge from the neural original network. Finally, in section of Conclusion, the paper is summarized, and future work is discussed.

## Materials and Methods

To measure the electrical activity of cultured neurons, we used a high-density CMOS microelectrode array <sup>1</sup>(Frey et al., 2010). The CMOS array is pictured in figure 1 (a). This array is an emerging instrument for investigating the spatio-temporal activity of cultured neurons in detail. The CMOS array has 11,011 recording sites with an inter-electrode distance of 18  $\mu\text{m}$ , i.e., in the order of cell body size, and a sampling rate of 20 kHz. This high spatio-temporal resolution allows precise recording of action potentials from the identified cell bodies of neurons. Using this high spatial resolution, we localized neural somata and recorded their activity.

<sup>1</sup>All procedures were approved by the institutional committee at the University of Tokyo, and were performed in accordance with the Guiding Principles for the Care and Use of Animals in the Field of Physiological Science of the Japanese Physiological Society.

This CMOS array is superior to conventional microelectrode array (MEA) (Sun et al., 2010; Eytan and Marom, 2006; van Pelt et al., 2004) in respect of spatio-temporal resolution: The locations of recording sites in conventional MEAs are predetermined, with an inter-electrode distance of  $200\text{ }\mu\text{m}$ , so that it is difficult to identify signals from an individual cell, and neurons far from these recording sites are not included. Alternatively, optical imaging can be used to study the  $\text{Ca}^{++}$  dynamics of any neuron of interest; however, the temporal resolution is not high enough to characterize the action potentials of each neuron.

Figure 1: High-density CMOS array (a) Appearance. (b) Interval of each electrodes is close to the cell body size.

**Dissociated neural culture** The neural cultures were prepared from the cerebral cortex of E18 (embryonic 18) Wistar rats. The cortex was triturated with trypsin and dissociated cells were plated and cultured on high-density CMOS microelectrode arrays coated with polyethylenimine and laminin. For the first 24 h, the cells were cultured in neurobasal medium containing 10% horse serum, 0.5 mM GlutaMAX and 2% B-27 supplement. After the first 24 h, half of the medium was replaced with growth medium in the form of Dulbecco's modified Eagle's medium with 10% horse serum, 0.5 mM GlutaMAX, and 1 mM sodium pyruvate. During the cell culturing, half of the medium was replaced once a week with the growth medium. The cultures were placed in an incubator at  $37\text{ }^{\circ}\text{C}$  with an  $\text{H}_2\text{O}$ -saturated atmosphere consisting of 95% air and 5%  $\text{CO}_2$ . We prepared for two conditions with different densities of neurons. The denser chips had 35,000 cells plated, denoted as Chip#1D and Chip#2D, while the sparser ones had 14,000 cells, termed Chip#1S and Chip#2S.

**Recording of neural activity** Neural activity was recorded with high-density CMOS microelectrode arrays. Before the neural somata activity was recorded, almost all of the 11,011 electrodes were scanned to obtain an electrical activity map with which we estimated the locations of the somata. A scan session consisted of 95 recordings; each recording was conducted for 60 sec with about 110 electrodes that were selected randomly, while avoiding overlap with already selected electrodes. An

electrical activity map was obtained from the scanned data by calculating the average height of the spikes for every electrode. We assumed that the neural somata were near the local peaks in the Gaussian-filtered electrical activity map. About 100 of the higher-level peaks were selected, and then the nearest electrodes were selected for recording. If the number of local peaks was fewer than 126, then all the peaks were selected. The electrical activity of the selected electrodes was recorded for 30 min. All recordings were done at a 20-kHz sampling rate using the LimAda spike detection algorithm (Wagenaar et al., 2005) with a threshold of 5. Unexpected double-detected spikes were removed from the data before the analysis was conducted.

## Results and Discussion

### Simple observation of activity patterns

First, we observed the activation patterns of the neurons by examining the time series of the neural spikes. Figure 2 shows examples of raster plots of Chip#1D and Chip#1S. Chip#2D and Chip#2S showed similar tendency to their respective counterparts (data not shown). The data plotted here are a compressed version of the raw data with a different bin-length, which is denoted by  $\Delta t$ . Namely, the spikes within the same bin are regarded as one spike. If  $\Delta t$  is smaller, the time series represents single spikes generated from each single neuron, while a larger  $\Delta t$  represents the macroscopic behavior created by an ensemble of neurons. In the figure 2, the data are plotted in  $\Delta t = 0.6\text{ ms}$  and  $100\text{ ms}$ . At the top of each raster plot, the activation ratio is displayed. We chose  $\Delta t = 0.6\text{ ms}$  and  $100\text{ ms}$  as the examples by two reasons; a single spike of neurons lasts around  $1\text{ ms}$ , while, observably from figure 2, synchronous activation of neurons is detected around  $\Delta t = 10\text{--}100\text{ ms}$ . Therefore, we took  $\Delta t = 0.6\text{ ms}$  to capture interaction between individual cells (microscopic), while  $\Delta t = 100\text{ ms}$  is to observe collective activities generated from an ensemble of neurons (macroscopic).

As shown in figure 2(a) right, the Chip#1D neurons at days *in vitro* 7 (DIV 7) are activated intermittently in synchronization. This activation pattern was burst synchronization, in which an ensemble of neurons has active and silent phases; in the active phase, synchronous activation of the neurons is intermittently observed. The burst synchronization is a typical activation pattern observed in cell cultures (Maeda et al., 1995). On the left of figure 2(a), the silent phase of the neural activation is magnified with  $\Delta t = 0.6\text{ ms}$ . Neural spikes are observed sparsely, which suggests that each neurons was activated independently from others.

On the other hand, at the later stage (DIV 14) of the Chip#1D, burst synchronization is not observed (figure 2 (b) right). Instead, we observed each neurons shows different activation patterns; i.e., some neurons were activated

almost all the time, some showed spikes less often, and others remained silent. These neurons seem to be activated at different frequencies. The left of figure 2(b) shows that, at  $\Delta t = 0.6$  ms, a single spike is followed by another, which suggests that one single spike can activate another. In contrast, Chip#1S showed the burst synchronization throughout the entire recoding period (figure 2(c) and (d)).

To summarize the results thus far, burst synchronization was observed in two conditions; in the earlier developmental stage of the dense cell condition, or in the sparse cell condition. In those cases, any single spikes hardly activate another. In the later stage of the dense cell condition, the neurons spiked at various frequencies, where single spikes induce others. This tendency is explained by the maturity of synapses. At the earlier developmental stage, the synapses are not mature; therefore, a single spike cannot activate another. Still, if the neurons send spikes at the same time (synchronous bursts), the signals become enough strong to activate each other. In contrast, at the later stage of development, the synapses were enough strong to transmit a single spike from one neuron to another.

### Single cell activity evaluated with ISI

In the next step of the analysis, we quantified the activation patterns of each neuron. Therefore, we analyzed the interspike intervals (ISI) distribution of the neural activity. Figure 3 (a) depicts examples of ISI distribution recorded from putative single neurons cultured in Chip#1D. In the earlier culture stage (DIV 7; figure 3 (a) left), exponential decay was observed, while the neurons tended to obey the power law at DIV 14 (right figure). To quantify this tendency, we plotted the ISI frequency on a logarithmic scale, and we fit the slope with a straight line by the least squared method. If the ISI distribution follows the power law, the distribution should be a straight line, so that the R-squared value is an index of fitting the power law.

Figure 3(b) shows the average of the R-squared values over each neuron; the values tended to increase in Chip#1D, Chip#1S and Chip#2S. Especially, Chip#1D shows a drastic increase at DIV 10, which suggests the neural activity became closer to the power law. Chip#2D also shows a higher R-squared value throughout the entire recording period. The recordings for Chip#2D started from DIV 17, which explains the result is similar to the later stage of Chip#1D.

The power law means that each neuron exhibited a wide range of ISIs. It may be related to the observation from the raster plots (figure 2), which showed that a wide range of frequencies between neurons were observed at the later development stage. To sum them up, a broader range of time scales likely emerges after synaptic maturation. However, from this ISI analysis, it is not possible to understand how those cultured neurons interact with each other to generate the activity patterns. In the next part, we then investigated neuron connectivity.

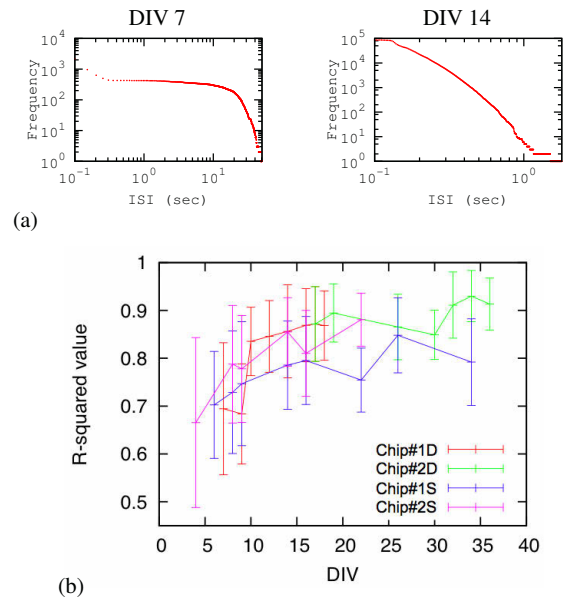

Figure 3: (a) Examples of the ISI distribution of neural activity recorded in a cell on Chip#1D. The X and Y axes depict the ISI logarithm and frequency respectively. The two figures show the results for each 7 and 14 DIV. The estimated exponents for DIV 7 and 14 are -1.40(0.57) and -3.77(0.57). The values inside the parentheses denote the R-squared values of the regression lines. (b) Change in the R-squared values with DIV. The R-squared value is obtained from a regression line fit to the ISI distribution, which is plotted on a logarithmic scale. When the R-squared value is closer to 1.0, the ISI distribution is more likely to obey the power law.

### Cell-cell interaction inferred with transfer entropy

We used transfer entropy (TE) to estimate the effective connectivity for transferring information from one neuron to another. TE measures directed information transfer, which detects causal relationship between two time series (Schreiber, 2000; Lizier et al., 2011; Staniek and Lehnertz, 2008; Bertschinger et al., 2008). For instance, higher TE from one neuron to another indicates that the first neuron strongly affects the second. Therefore, TE enables us to find the functional synaptic connectivity. We defined the TE, and then applied it to artificial neural networks to ensure the validity of TE to estimate effective connectivity. Finally, we applied TE to the cultured neural cells to infer their topology.

**Definition of transfer entropy** Information is measured with Shannon entropy, which quantifies the amount of uncertainty associated with a system  $X$ . Specifically, Shannon entropy of a system  $X$  is defined as:

$$H(X) = - \sum_{x \in X} p(x) \log p(x), \quad (1)$$

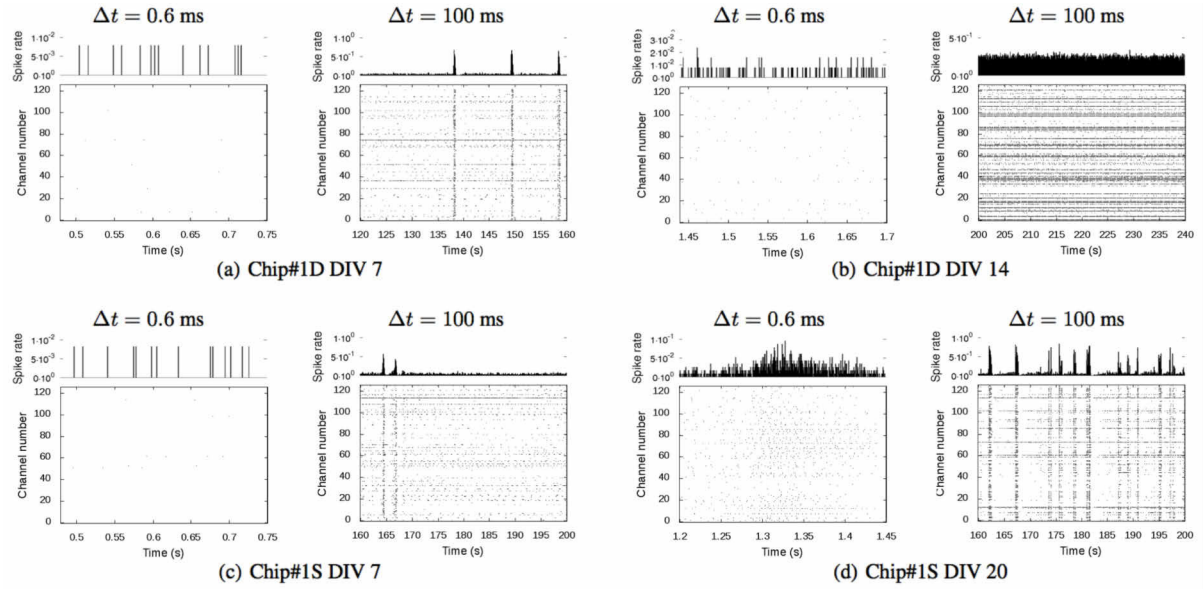

Figure 2: Examples of the raster plot of the cultured neurons. The X axis denotes time (s). The Y axis represents the indexes of the recoding channel, where one channel can be considered as one neural cell. The subfigures at the top of the raster plots shows the spike rate. (a) - (d) Results for Chip#1D and Chip#1S with different DIVs.  $\Delta t = 0.6$  ms (microscopic) and 100 ms (macroscopic).

where  $p(x)$  denotes the probability of  $x$  ( $x$  is an event of  $X$ ). To evaluate the dependency between  $X$  and  $Y$ , mutual information ( $MI$ ) is defined as follows:

$$\begin{aligned} MI(X, Y) &= H(X) - H(X|Y) \\ &= H(Y) - H(Y|X). \end{aligned} \quad (2)$$

$H(X|Y)$  means conditional entropy, i.e., the uncertainty of  $X$  when  $Y$  is known. Therefore,  $MI(X, Y)$  suggests a decrease in the uncertainty of  $X$  when  $Y$  is known.  $MI(X, Y)$  measures the dependency between  $X$  and  $Y$ ; so that this variable cannot quantify a causal relationship between them.

TE measures the causal relationship between  $X$  and  $Y$  by calculating the past history. The TE from  $X$  to  $Y$  is denoted by  $T_{X \rightarrow Y}$ , which is written as:

$$\begin{aligned} T_{X \rightarrow Y} &= H(y_{n+1}|y_n^{(k)}) - H(y_{n+1}|y_n^{(k)}, x_n^{(l)}) \\ &= \sum_{n=0}^{N-1} p(y_{n+1}, y_n^{(k)}, x_n^{(l)}) \log \frac{p(y_{n+1}|y_n^{(k)}, x_n^{(l)})}{p(y_{n+1}|y_n^{(k)})} \end{aligned} \quad (3)$$

where  $n$  is the current time step, and  $y_t^{(k)}$  and  $x_t^{(l)}$  are the past variables with length  $k$  and  $l$  respectively (i.e.,  $y_t^{(k)} = \{y_t, y_{t-1}, \dots, y_{t-k+1}\}$  and  $x_t^{(l)} = \{x_t, x_{t-1}, \dots, x_{t-l+1}\}$ ). When the next step of  $Y$  ( $= y_{n+1}$ ) is conditioned from the past history of  $X$  ( $= x_n^{(l)}$ ), then  $H(y_{n+1}|y_n^{(k)}, x_n^{(l)})$  takes a smaller value than  $H(y_{n+1}|y_n^{(k)})$ . If  $y_{n+1}$  is independently determined from

the past history of  $X$ , then the two components will have the same value. Therefore,  $TE_{X \rightarrow Y}$  measures the causality of  $X$  to  $Y$ .

**Settings of artificial neural networks** TE analysis was first applied to a computational neural model. The model was built around Izhikevich neurons connected through artificial synapses (Izhikevich, 2003). The Izhikevich neurons form a simple model of cortical neurons that is implemented by a system of two differential equations modeling the membrane potential and the refractory period. When the membrane potential reaches a threshold value (for instance, 30 mV), a spike is emitted. This spike is transferred to post-synaptic neurons through some shared synapses. The voltage on arrival is the original spike strength, modulated by the efficacy of the synapses. For instance, an initial spike of 30 mV traveling on a synapse with an efficacy of 0.5 delivers a voltage of 15 mV to the post-synaptic neuron. Every synapse has a delay of 1 ms between the time of emission and the arrival of a spike.

The complete model is composed of seven neurons: four input neurons receiving randomly generated external stimulations, two internal neurons and one output neuron. The parameters for the Izhikevich neurons correspond to the regular spiking model ( $a = 0.02$ ,  $b = 0.2$ ,  $c = -65$  mV and  $d = 6$ ). Different types of connectivity patterns have been tested, ranging from fully inter-

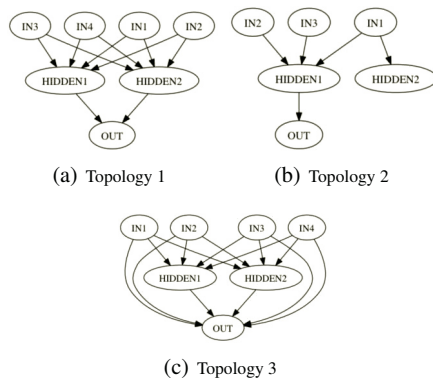

Figure 4: Topology of the original network used in the computer simulation.

connected to sparse (figure 4 (a)–(c)). The strength of the connection is randomly assigned based on uniform distribution. Every update of the model represents a 0.1-ms step in time, which ensures the model’s mathematical stability. The total duration of a test is 1000 s, which corresponds to 10,000,000 updates of the model.

**Estimated connectivity of the artificial network** From the time series of the artificial neural activity, we calculated the TE from one neuron to another. Using the TE, we estimated the network structure of the artificial neurons. A synaptic connection from one to the other was assumed when the TE between two neurons was higher than the threshold. Then, we compared the topology of the reconstructed network and the original network shown in figure 4 (a)–(c). The number of false edges for each topology is shown in figure 5.  $\Delta t$  in this figure is the same one as previously used, which represents the bin-length of the compressed time series. This figure shows that the optimal parameter set to reconstruct the original topology depends on the dimension of the past variables ( $k$  and  $l$ ) and  $\Delta t$ .

The result ensures that the effective connectivity to transmit signals by TE is estimated. However, a good approximation depends on the dimension and time scale  $\Delta t$ . We used various  $\Delta t$  to get a good approximation of the effective connectivity in the cultured neurons.

**Estimated connectivity of cultured neurons** Figure 6 shows some examples of the estimated network structure of neurons. This depicts the network of Chip #1D DIV 14 with different  $\Delta t$  ( $= 0.6$  ms, 1 ms and 10 ms). An edge is drawn if the TE from one neuron to another is higher than the threshold, which was set to 0.00001. The threshold is determined arbitrarily, but to display dynamical change in connectivity patterns. The first observation about this figure is that different topology is structured depending

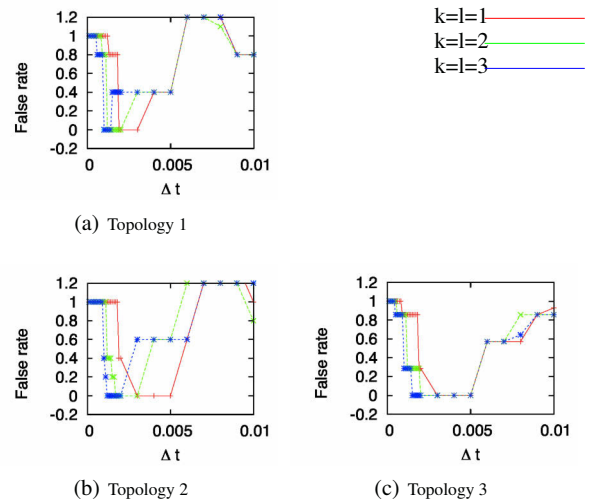

Figure 5: Number of false connections with different  $\Delta t$  values. The threshold was set to 0.005.

on  $\Delta t$ . As is shown with the artificial neural network, each connection may not have the same optimal  $\Delta t$  to estimate connections. Based on (Oka and Ikegami, 2013), we used the optimal  $\Delta t$  to understand the information flow in the network.

Figure 6: Examples of the network structure of the information flow obtained from TE. The data used here is from Chip#1D DIV 14.  $\Delta t = 0.6$  ms, 1 ms, and 10 ms. The TE threshold to draw edges was set to 0.00001.

### Optimal time scale to convey information

As observed, the cell-cell interaction estimated from the TE analyses depends on the time scale  $\Delta t$ , so that we evaluated the optimal  $\Delta t$  to estimate the network structure better. We defined the optimal  $\Delta t$  as  $\Delta t^*$  that maximizes TE.  $\Delta t^*$  was calculated for each directed pair of neurons. Information was considered to be transferred most effectively with the  $\Delta t^*$ . Therefore, the  $\Delta t^*$  exhibits effective synaptic connectivity from each neuron to another.

Figure 7 (a) and (b) depict  $\Delta t^*$  from one neuron to another in Chip#1D and Chip#1S respectively. Edges are

drawn if TE at the  $\Delta t^*$  is larger than the threshold ( $= 0.00001$ ; same as the one used above). The color indicates the value of  $\Delta t^*$ , where red represents  $\Delta t^*$  smaller than 10 ms and blue indicates larger. We defined  $\Delta t^* = 10$  ms as a threshold to assign color, because burst activity was observably detected with  $\Delta t$  larger than 10 ms (figure 2). Hereafter, we call  $\Delta t > 10$  ms “the smaller  $\Delta t^*$ ”, and  $\Delta t \geq 10$  ms “the larger  $\Delta t^*$ ”, where we divide the activity pattern into microscopic and macroscopic using this threshold. Additionally, figure 8 shows the  $\Delta t^*$  distribution.

Figure 7 (a) and 8 (a) show that, at an earlier stage of the development of Chip #1D, a larger  $\Delta t^*$  is mainly observed. The number of the smaller  $\Delta t^*$  increases at DIV 12, which means a causal relationship between each neurons is observed within a shorter period. This is consistent with the observation in figure 2 (b) that a single spike activates another neuron within a short period. For Chip#2D, a smaller  $\Delta t^*$  was observed throughout the entire recording period (figure 8(b)). Chip#2D was recorded beginning at DIV 17, which is relatively later compared with those of the other chips. That can explain why Chip#2D was similar to the later stage of Chip#1D.

Interestingly, the smaller  $\Delta t^*$  observed in Chip#1D and Chip#2D coexisted with the larger  $\Delta t^*$  (figure 8 (a) and (b)). This suggests that neural activity occurs at a wider range of time scales. Figure 7 (a) shows that the intervening neurons have red and blue edges, which implies microscopic and macroscopic activity to exchange information with each other. However, the frequency of the smaller  $\Delta t^*$  in Chip#1S and Chip#2S was low throughout the entire recording period (figure 7(b), 8(c-d)). Still, similarly to the result for the dense cell condition, as DIV increased, the number of the smaller  $\Delta t^*$  grew.

## Conclusion

We characterized neural activity cultured on a high-density CMOS array. The neurons showed different activation patterns depending on the density and age (days *in vitro*; DIV). The neurons did not receive external inputs, but still spontaneously evolved. The neurons were cultured in two different conditions, i.e., dense or sparse.

When the cell density was high, the neurons showed burst activity first, and afterward, each neural cell activated at a different frequency (figure 2 (a), (b)). Some were activated all the time, some showed spikes intermittently, and others remained silent. The ISI distribution of each cell became closer to the power law as the DIV increased (figure 3), which suggests a single cell evolved to show a wider range of time scales. These results suggest that neural activity exhibits a wider range of time scales as the synapses mature. This tendency was shown clearly with TE (figure 7). At the earlier stage of development, TE was mainly optimized at a larger time scale, while, at the later stage, TE was also optimized at a smaller time scale (figure 8).

A mature human brain is a collection of functional networks, each of which corresponds to a different cognitive function (Fair et al., 2009). In this paper, we insist that even a neural network on a glass plate spontaneously develops “functional networks”, which can be distinguished in terms of the time scale determined by effective information transfer. Without relevant sensory input, we cannot say the networks are functional in the proper context of brain science; however, we speculate that the spontaneous development of “functional networks” is a candidate for the brain functional network. In future work, we will connect the neurons with a navigation robot to see how the functional networks actually “function” as cognitive modules.

The emergence of autocatalytic structures in model chemistries has been a prominent subject throughout the history of artificial life research (Rasmussen (1985); Farmer et al. (1986); Kauffman (1986); Rasmussen (1989); Hordijk et al. (2011) and others). Most of these works have been concerned with the likelihood of finding autocatalytic sets in a population of random cross-catalytic molecules. Here, in contrast, we study how the detailed sequence structure determines the properties of the emergent cooperative structures. In particular, we study a system of binary polymers, where each polymer can replicate itself by exact ligation of two matching subsequences. We report the emergence of stable cooperative structures with high equilibrated polymer concentrations together with a quantitative connection between the details of the sequence and the frequency as well as the stability of the evolving cooperative structures. These findings could have implications for early earth information polymers as well as the design of protocell information polymer networks.

In the simplest realization, we allow for decomposition, random ligation, and autocatalytic ligation of polymers via the three reactions

where  $l$  and  $m$  are strings of arbitrary length over the alphabet  $\{0, 1\}$  and  $l.m$  denotes string concatenation.  $c_0$ ,  $c_1$ , and  $c_2$  are the respective reaction rates.

If random ligation is comparably rare ( $c_1 \ll c_2 \bar{x}$  for some typical species size  $\bar{x}$ ), the system exposes several unexpected dynamics: (1) out of exponentially many possible strings, stochastic simulation (Gillespie (1977)) repeatedly selects only very few specific strands; (2) the selected populations are strikingly regular — with the motif 010101 being most common; (3) the occupancy of most strings in a population fluctuates around a constant value independent of the length of the string (c.f. Fig. 1) All these properties are in direct contrast to a scenario without catalysis ( $c_2 = 0$ ).

Most of these features can be explained analytically. Examining the reaction kinetic equations reveals that every string of a stationary state must be accompanied by its substrings which are generated through decomposition. We call the longest members of a population its “chiefs” and the sets of their substrings “clans”. In the limit  $c_1 \rightarrow 0$ , chiefs can have an arbitrary occupancy, whereas all non-chief members of a population equilibrate to a constant value determined by the rates of autocatalysis and decomposition as  $\bar{x} = \sqrt{c_0/c_2}$ . Linear stability analysis of several hundred exemplary stationary states confirms that these populations are indeed stable states. Under purely random ligation ( $c_2 = 0$ ), on the other hand, the stationary strand distribution is exponential in strand length  $k$ :  $x_k = (c_0/c_1)e^{-b|k|}$ , where  $b$  is given by the boundary condition.

When starting from a pool of monomers, the ligation dynamics will transport most of the material from the monomers to the emerging front of a chief-clan structure. Rare random ligations slowly expand this front by forming new chiefs. To explain why regular chiefs, such as 01010101, are selected more frequently than irregular ones we note: (i) regular chiefs require the formation of fewer intermediate chiefs: formation of 01010101, for example, requires three random ligations, whereas formation of 01101100 requires at least five ligations; (ii) regular chiefs offer more reaction pathways than irregular ones, as substrings of irregular strings have to ligate in correct order; (iii) population size strongly impacts the reaction rates which results in selection of certain regular sequence patterns.

Thoroughly calculating the likelihoods of forming given chief structures from monomer pools by occasional random ligation and subsequent equilibration, confirms quantitatively that this is indeed the driving mechanism of selection in the simulation results. These calculations also suggest that the “twotowers” structure (Fig. 1.d) becomes less likely with increasing system size, whereas system size shows little impact on the probabilities to obtain other regular structures.

While autocatalysis and degradation stabilize clan structures, random ligation introduces fluctuations in the sys-

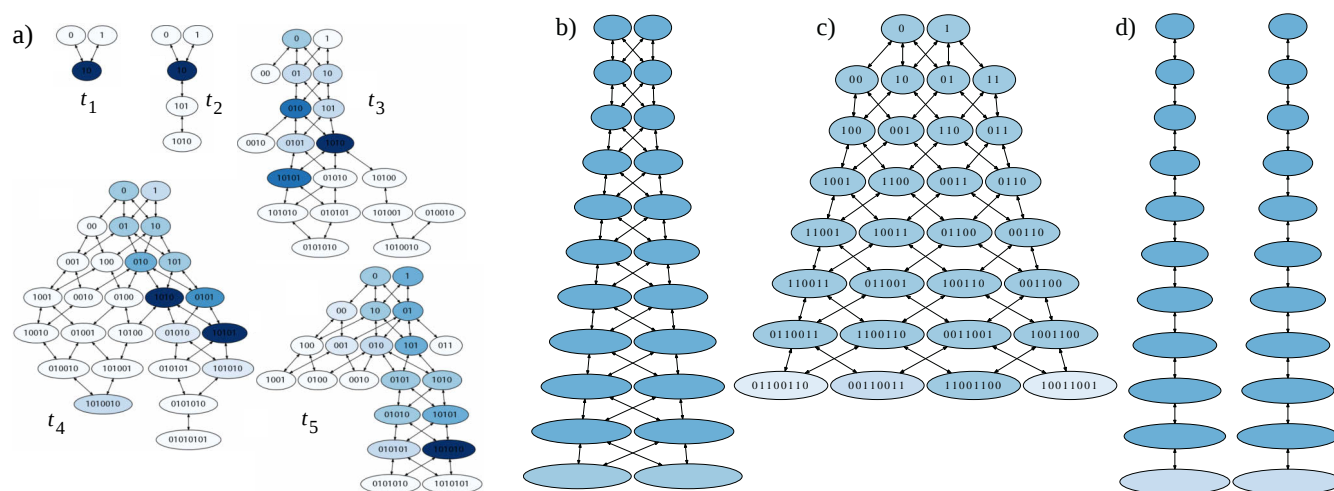

Figure 1: Representatives of the three most prominent stable cooperative structures (b)-(d) found in stochastic simulation at  $t = 100$ , together with snapshots (a) of the evolutionary formation of structure (b). More than 4000 simulations with parameters  $c_0 = 1$ ,  $c_1 = 10^{-10}$ ,  $c_2 = 10^{-7}$  and initial condition  $x_0 = x_1 = 100,000$  are performed. Graphs (b)-(d) show the average of all respective members of the three biggest clusters. Results have been aggregated using single-linkage hierarchical clustering using cosine distance. Nodes represent strings with molecular occupancy greater than or equal to 100, where darker color means larger population. Links among non-adjacent layers are omitted for clarity. 44% of the simulations resulted in a bootlace structure generated by the chiefs containing the motif 10101010 (b); another 19% of the simulations produced a pinecone structure with chiefs containing the motif 00110011 (b); and another 2% of the simulations generated the two-tower structure (d) with chiefs 00000000 and 11111111. The shown structures cover more than 65% of the simulations.

Figure 2: Fluctuations seen in the cosine similarity between an initial structure at  $t = 0$  and the one at  $t$  for (a) bootlace (solid line) and twotowers (dotted line), and (b) different pinecone structures. Note different y-axis scales.

tem. Fig. 2 shows fluctuations observed in populations drawn from the most prominent selected clan structures. While “bootlace” and “twotowers” structures (Fig 1.b and d) are relatively robust against fluctuations and reestablish the initial population after perturbations, “pinecone” structures (Fig 1.c) are more susceptible to randomness and the populations move between several metastable states which correspond to the four possible competing chiefs seen in Fig 1.c. This demonstrates how random events through selection generate punctuated equilibria in the evolutionary dynamics.

The dynamics and evolutionary potential of these systems with open boundary conditions (chemostat dynamics) remain to be studied, as well as the impact of a chemically more realistic, but also more complex, template complementarity based matching with possible sequence overhang.

## Abstract

Boolean networks under different deterministic updating schemes are analyzed. It is direct to show that fixed points are invariant against changes in the updating scheme, nevertheless, it is still an open problem to fully understand what happens to the limit cycles. In this paper, a theorem is presented which gives a sufficient condition for a Boolean network not to share the same limit cycle under different updating modes. We show that the hypotheses of the theorem are sharp, in the sense that if any of these hypotheses do not hold, then shared limit cycles may appear. We find that the connectivity of the network is an important factor as well as the Boolean functions in each node, in particular the *XOR* functions.

## Introduction

Boolean networks were introduced by S. Kauffman (Kauffman, 1969) and R. Thomas (Thomas, 1973) as a mathematical model of gene regulatory networks. It has been used to model, for example, the floral morphogenesis of *Arabidopsis thaliana* (Mendoza and Alvarez-Buylla, 1998), the fission yeast cell cycle (Davidich and Bornholdt, 2008; Goles et al., 2013), and the budding yeast cell cycle (Li et al., 2004; Goles et al., 2013). Formally, let  $\mathbf{x} = \{x_1, \dots, x_n\}$  be a finite set with  $x_i \in \{0, 1\}$  for  $i = 1, \dots, n$ . Let  $N = (G, F, \pi)$  be a Boolean network, where  $G = (V, E)$  is a digraph;  $V$  being the set of  $n$  nodes and  $E$  the set of edges.  $F$  is a Boolean function,  $F : \{0, 1\}^n \rightarrow \{0, 1\}^n$  composed of  $n$  local functions  $f_i : \{0, 1\}^n \rightarrow \{0, 1\}$ . Each local function  $f_i$  depends only on the variables belonging to the neighborhood  $V^-(i) = \{j \in V | (j, i) \in E\}$ . The indegree of vertex  $i$  is  $|V^-(i)|$ , and  $\pi$  is an arbitrary order to update the nodes  $\pi : \{1, \dots, n\} \rightarrow \{1, \dots, n\}$ . For example, the parallel or synchronous updating mode (or scheme) has  $\pi(i) = 1$  (every node is updated at the same time), whereas, for the sequential one,  $\pi$  is a permutation. A combination of the parallel and the sequential updating mode is the block-sequential where the set of nodes, for a given sequence, is partitioned into blocks. The nodes in a same block are updated in parallel, but blocks follow each other sequentially. Overall, there are an exponential number of updates. In fact,

if the network has  $n$  nodes, the number of updates is given by Demongeot et al. (2008):

$$T_n = \sum_{k=0}^{n-1} \binom{n}{k} T_k, \quad T_0 = 1.$$

Without loss of generality,  $f_i(\mathbf{x}) = f_i(x_1, \dots, x_n)$  will be used sometimes, although it should be clear to the reader that the local function really depends only on the variables in the neighborhood. Since the updating schemes are repeated periodically and the hypercube is a finite set, the dynamics of the network converges to attractors which are fixed points, i.e vectors such that  $x_i = f_i(\mathbf{x})$  for any  $i$ , or limit cycles, defined by  $x_i^{t+p} = x_i^t$  for  $i = \{1, \dots, n\}$ , where  $p > 1$  is the period. In this paper we will consider limit cycles that have *non-constant* values (a constant node does not change its value during the limit cycle) within it <sup>1</sup>.

One of the first to compare updating modes was F. Robert (Robert, 1986) for the parallel and sequential update. More recently, the robustness of such networks related to changes in the updating modes have been studied in Goles and Salinas (2008), where the authors prove that networks with monotonic loops<sup>2</sup> can not share limit cycles between the parallel and the sequential update. Furthermore, a first step to understand the different updates was done in Elena (2009); numerical experiments, under small threshold networks ( $n = 3$ ) were carried out in order to exhibit the different dynamics for every updating mode. Also, theoretical tools were developed in order to classify dynamics under different updating modes as well as to build efficient algorithms (Aracena et al., 2009; Montalva, 2011). In Goles and Noual (2012) a theoretical study of the dynamics of disjunctive networks under all updating schedules was presented. In Ruz and Goles (2013), results from reverse engineering synthesizing threshold Boolean networks with predefined limit cycles, showed that shared limit cycles, of length two, from parallel to sequential updates, were obtained for networks with indegree 3 and indegree 5.

<sup>1</sup>If there is a constant node, one may consider a new network, smaller than the original one, with non-constant nodes.

<sup>2</sup>A loop is a self connected node.

In this work, we characterize a class of Boolean network such that, two different updating modes (or a class of them) do not share non-constant limit cycles. We will see that connectivity plays an important role in this problem, in fact, if the digraph admits nodes of indegree 3, then we may find networks such that, for a specific Boolean function, the parallel and sequential updates (among others) share non-constant limit cycles (see Fig. 1). Therefore, we restrict

Figure 1: a) Strongly connected digraph  $G$  with  $|V^-(1)| = 3$ . b) Limit cycle shared by  $N_1 = (G, F, \pi_1)$  and  $N_2 = (G, F, \pi_2)$  where  $\pi_1 = \varphi$  is the parallel updating mode,  $\pi_2 = (2)(3)(4)(1)$  and  $F = (Y_1, \dots, Y_4)$ .

our study to digraphs of indegree at most 2. In this context, we have 16 two-input Boolean functions. It is easy to see that 14 of these functions are *canalizing* (Fogelman et al., 1982) in, at least, one input (i.e., when this input is fixed in a Boolean value  $a$ ,  $f(a, x) = f(a, \bar{x})$ ). We will prove that for the majority of the canalizing functions, one may find different updating schemes such that they share non-constant limit cycles; the exception will be the case when the function is *positive canalizing*<sup>3</sup> in its own input. In this case, the sequential and the parallel updates do not share non-constant limit cycles, which is a particular case of the result proved in Goles and Salinas (2008). Further, if the local function is *non-canalizing* (i.e., the *XOR* ( $x \oplus y = 1 \Leftrightarrow x \neq y$ ) or the *EQUIVALENCE* ( $f(x, y) = 1 \Leftrightarrow x = y$ )), we prove that, for any network of indegree at most 2 and a huge family of updating modes, the networks do not share non-constant limit cycles. In addition, for the particular case of the parallel and sequential updates, when the digraph is strongly connected we have the same result. We point out that the *XOR* and *EQUIVALENCE* functions are not monotone in any variable. It was remarked in Kauffman (1969); Walker and Gelfand (1979); Fogelman et al. (1982); Noual et al. (2012) that these kind of networks admits very long limit cycles, also, their dynamics are very sensitive to the variation of the updating mode.

<sup>3</sup>A function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  is *positive canalizing* on input  $i$  if for every Boolean vector  $x$ ,  $f(x_1, \dots, x_{i-1}, 0, x_{i+1}, \dots, x_n) \leq f(x_1, \dots, x_{i-1}, 1, x_{i+1}, \dots, x_n)$ .

## Unshared limit cycles in Boolean networks

The main result of this section is Theorem 1 that shows a sufficient condition such that a Boolean network can not share limit cycles when it is updated by different updating modes. After, we will deduce a particular case for unshared limit cycles between the parallel and any other updating mode. Next, we will show that the hypotheses of the Theorem 1 are sharp (if we change any of them, shared limit cycles may appear). Finally, we will also show that such sufficient condition is not a necessary one.

In order to prove the main result we will assume that the indegree is  $\leq 2$ , since shared cycles may appear when the indegree is  $\geq 3$ . On the other hand, we define appropriate partitions of the different updating modes.

Let  $G$  be a digraph and  $S_n$  the set of all update schedules over  $V$ . For  $i \in V$  such that  $V^-(i) = \{u, v\}$ , we define the following partition of  $S_n$ :

$$\begin{aligned} P_1(i) &= \{s \in S_n : s(u) < s(i) \leq s(v)\} \\ P_2(i) &= \{s \in S_n : s(v) < s(i) \leq s(u)\} \\ P_3(i) &= \{s \in S_n : s(i) > s(u) \wedge s(i) > s(v)\} \\ P_4(i) &= \{s \in S_n : s(i) \leq s(u) \wedge s(i) \leq s(v)\} \end{aligned}$$

and the *XOR* family  $\mathcal{F} \equiv \{x_u \oplus x_v, x_u \oplus x_v \oplus 1, x_u, x_u \oplus 1\}$ , where  $x \oplus y = 1 \Leftrightarrow x \neq y$ .

If  $i \in V$  is such that  $V^-(i) = \{u\}$ , we define the following partition of  $S_n$ :

$$\begin{aligned} P_1(i) &= P_2(i) = \emptyset \\ P_3(i) &= \{s \in S_n : s(i) > s(u)\} \\ P_4(i) &= \{s \in S_n : s(i) \leq s(u)\} \end{aligned}$$

In this case, the family is reduced to  $\mathcal{F} \equiv \{x_u, \bar{x}_u\}$ .

**Theorem 1** (Unshared limit cycles). *Let  $G$  be a digraph such that  $1 \leq |V^-(i)| \leq 2, \forall i \in V$  and consider a Boolean network  $N_1 = (G, F, \pi_1)$  that admits a limit cycle  $C$ . If every  $f_i \in \mathcal{F}$ , then, for any updating mode  $\pi_2 \neq \pi_1$  verifying that:*

$$\begin{aligned} \text{Update condition: } &\exists i \in \{1, \dots, n\}, \pi_1 \in P_4(i) \\ &\text{and } \pi_2 \in P_1(i) \cup P_2(i) \cup P_3(i), \end{aligned}$$

*the dynamics associated to the updates  $\pi_1$  and  $\pi_2$  do not share the same limit cycle  $C$ .*

*Proof.* Let  $N_1 = (G, F, \pi_1)$  be a Boolean network of  $n$  nodes such that  $1 \leq |V^-(i)| \leq 2, \forall i \in V$  and that admits a non-constant limit cycle  $C$  associated to the updating mode  $\pi_1$ . Moreover, suppose that  $f_i \in \mathcal{F}, \forall i \in \{1, \dots, n\}$ .

First, note that for this kind of functions:

$$\forall i \in \{1, \dots, n\}, \forall x \in \{0, 1\}, f_i(0, x) \neq f_i(1, x) \quad (1)$$

We denote by  $x_j^{\pi_1}(t)$  and  $x_j^{\pi_2}(t)$  the state of node  $j$  at time  $t$  for the updating modes  $\pi_1$  and  $\pi_2$  respectively.

Let  $\pi_2 \neq \pi_1$  be a given updating mode verifying (1) for some  $i \in V$  such that  $V^-(i) = \{u, v\}$  and suppose on the contrary that  $N_2 = (G, F, \pi_2)$  has the same non-constant limit cycle  $C$  of  $N_1$ , i.e:

$$\forall j \in \{1, \dots, n\}, \forall x^{\pi_2} \in \{0, 1\}^n \cap C : x_j^{\pi_2}(t) = x_j^{\pi_1}(t) \quad (2)$$

For  $i$  as above, we have that  $\pi_1 \in P_4(i)$  and the following three cases are possible:

**Case 1:**  $\pi_2 \in P_1(i)$ . Then the updates are computed by

$$x_i^{\pi_1}(t+1) = f_i(x_u^{\pi_1}(t), x_v^{\pi_1}(t)) \quad (3)$$

$$x_i^{\pi_2}(t+1) = f_i(x_u^{\pi_2}(t+1), x_v^{\pi_2}(t))$$

$$\stackrel{\text{by (2)}}{=} f_i(x_u^{\pi_1}(t+1), x_v^{\pi_1}(t)) \quad (4)$$

Because the variables in  $C$  are non-constant,  $x_u^{\pi_1}(t) \neq x_u^{\pi_1}(t+1)$ . Hence, we can assume w.l.o.g. that  $x_u^{\pi_1}(t) = 0$  and  $x_u^{\pi_1}(t+1) = 1$ . Replacing these values in (3) and (4) we have that:

$$x_i^{\pi_1}(t+1) = f_i(0, x_v^{\pi_1}(t)) \text{ and,}$$

$$x_i^{\pi_2}(t+1) = f_i(1, x_v^{\pi_1}(t))$$

Thus, due to (1) we have that  $x_i^{\pi_1}(t+1) \neq x_i^{\pi_2}(t+1)$  which contradicts (2).

**Case 2:**  $\pi_2 \in P_2(i)$ . This is similar to Case 1 but considering the calculations over  $v$ .

**Case 3:**  $\pi_2 \in P_3(i)$ . Then the updates are computed by

$$x_i^{\pi_1}(t+1) = f_i(x_u^{\pi_1}(t), x_v^{\pi_1}(t)) \text{ and,}$$

$$x_i^{\pi_2}(t+1) = f_i(x_u^{\pi_2}(t+1), x_v^{\pi_2}(t+1)) \stackrel{\text{by (2)}}{=} f_i(x_u^{\pi_1}(t+1), x_v^{\pi_1}(t+1))$$

$$= x_i^{\pi_1}(t+2) \stackrel{\text{by (2)}}{=} x_i^{\pi_2}(t+2) = \dots$$

This means that the state of vertex  $i$  must never change within  $C$ , which contradicts the assumption that each variable in the limit cycle is non-constant.

Finally, note that if  $V^-(i) = \{u\}$ , then the analysis of the case  $\pi_2 \in P_3(i)$  is similar to Case 3.  $\square$

**Corollary 1.** Let  $G$  be a strongly connected digraph such that  $|V^-(i)| \leq 2, \forall i \in V$  and consider the Boolean network  $N_1 = (G, F, \varphi)$  associated to the parallel updating mode,  $\varphi$ ,

that admits a limit cycle  $C$ . If every  $f_i \in \mathcal{F}$ , then, for any updating mode  $\pi \neq \varphi$ , the Boolean network  $N_2 = (G, F, \pi)$  does not share the same limit cycle  $C$ .

*Proof.* Let  $N_1 = (G, F, \varphi)$  be a Boolean network of  $n$  nodes that admits a non-constant limit cycle  $C$  associated to the parallel updating mode  $\varphi$ . Suppose also that  $G$  is strongly connected with  $|V^-(i)| \leq 2, \forall i \in V$ . The latter implies that:

$$1 \leq |V^-(i)| \leq 2, \forall i \in V \quad (5)$$

$$\varphi \text{ is the parallel updating mode} \Leftrightarrow \forall j \in V, \varphi \in P_4(j) \quad (6)$$

Moreover, suppose that  $f_i \in \mathcal{F}, \forall i \in \{1, \dots, n\}$ .

Let us prove the sufficient condition. Let  $\pi \neq \varphi$  be an updating mode. By (6), we have that  $\pi \in P_1(i) \cup P_2(i) \cup P_3(i)$ , for some  $i \in V$  such that  $V^-(i) = \{u, v\}$ . This, together with (5) and the assumptions made at the beginning gives us the hypotheses of Theorem 1, with  $\pi_1 = \varphi$  and  $\pi_2 = \pi$ , which guarantees that  $C$  is not a limit cycle of  $N_2 = (G, F, \pi)$ .

Finally, note that the above analysis is similar when  $V^-(i) = \{u\}$ .  $\square$

**Corollary 2.** If  $C$  is a limit cycle associated to the parallel updating mode of a Boolean network such that its digraph is a circuit, then,  $C$  is not shared by any other updating mode.

*Proof.* A circuit is a strongly connected digraph such that,  $\forall i \in \{1, \dots, n\}; |V^-(i)| = 1$  and  $f_i \in \mathcal{F} \equiv \{x_u, \bar{x}_u\}$ , where  $u \in V^-(i)$ . Thus, by Corollary 1,  $C$  is not shared by any other updating mode.  $\square$

**Remark.** In particular, we have that the parallel and the sequential updating modes do not share non-constant limit cycles.

Now, we will show the sharpness of the hypotheses of Theorem 1.

**Case 1: Not all the local functions are in  $\mathcal{F}$ .** In Fig.2a) we exhibit a strongly connected digraph  $G$  with  $|V^-(i)| \leq 2, \forall i \in V$  where the network  $N_1 = (G, F, \pi_1)$  admits a limit cycle  $C$  showed in Fig.2b) for the parallel update schedule  $\pi_1 = \varphi$  and the global function  $F = (Y_1, \dots, Y_4)$  defined in Fig.2b) as well. However, although there exists  $N_2 = (G, F, \pi_2)$  with  $\pi_2 = (2)(1, 3, 4)$  such that  $\pi_1 \in P_4(1)$  and  $\pi_2 \in P_1(1)$  as in the update condition of Theorem 1,  $C$  is shared anyway for both dynamics, because in this case, the local function  $Y_1 = X_2 \wedge X_3$  is not a XOR function. Similarly, we arrive to the same conclusion if we consider  $Y_1 = X_2 \vee X_3$  and, in general, given that every local function  $f(x, y)$  (different to a XOR function) is a combination of  $\wedge$  and  $\vee$ , we can construct other examples, as the above one, but for  $f$ .

Figure 2: Example for Case 1. Note that  $Y_1 = X_2 \wedge X_3$  is the only hypothesis that does not match with Theorem 1.

**Case 2: The update condition of Theorem 1 does not hold.** First, we consider the same strongly connected digraph  $G$  of Fig.2a). The network  $N_1 = (G, F, \pi_1)$  admits a limit cycle  $C$  showed in Fig.3 for  $\pi_1 = (2)(1, 3)(4)$  and the global function  $F = (Y_1, \dots, Y_4)$  where all its components, that depend of two variables, are *XOR* functions. However,  $N_2 = (G, F, \pi_2)$  with  $\pi_2 = (3)(1, 2)(4)$  also shares  $C$ , because in this case,  $\pi_1$  and  $\pi_2$  do not verify the update condition of Theorem 1. We remark that it is also possible to show an example for each case not included in the above condition.

Figure 3: Example for Case 2. Note that  $\pi_1 = (2)(1, 3)(4)$  and  $\pi_2 = (3)(1, 2)(4)$  do not verify the update condition of Theorem 1.

**Case 3: Accepting constant limit cycles.** Consider the strongly connected digraph  $G$  showed in Fig.4a). Note that  $|V^-(i)| \leq 2, \forall i \in V$ . On the other hand, consider the limit cycle  $C$  showed in Fig.4b) admitted by  $N_1 = (G, F, \pi_1 = \varphi)$  where its first component is constant and equal to one. Also, on this same figure,  $F = (Y_1, Y_2, Y_3)$  is defined with all its components being *XOR* functions. So, it is easy to check that  $N_2 = (G, F, \pi_2)$  with  $\pi_2 = (2, 3)(1)$  is such that  $\varphi \in P_4(1)$  and  $\pi_2 \in P_3(1)$  as in the update condition of Theorem 1, but,  $N_2$  also shares  $C$ .

**Case 4: The sufficient condition of Theorem 1 is not a necessary condition.** The sufficient condition of Theorem 1 for unshared limit cycles (i.e., to have *XOR* functions in all the nodes with indegree equal to two) is not a necessary

Figure 4: Example for Case 3. This constant limit cycle is the only hypothesis that does not match with Theorem 1.

condition. Consider the digraph of Fig.5a), the limit cycle  $C$  and  $F = (Y_1, Y_2, Y_3)$  of Fig.5b) verifying  $|V^-(i)| \leq 2, \forall i \in V$ . The network  $N = (G, F, \varphi)$  admits  $C$  as a limit cycle which is not shared by any other updating mode, in spite of the fact that  $Y_3 = X_1 \wedge X_2$  is not a *XOR* function.

Figure 5: Example showing that the sufficient condition of Theorem 1 for unshared limit cycles is not a necessary condition.

## Simulations

In order to see how common it is to find Boolean networks (BN) that share the same limit cycles for different updating schemes (or modes), we conducted an exhaustive study for  $n = 3$  updating all the BN (graph + local functions) with

indegree at most 2, which yields 46656 BN, under all the deterministic updating schemes, i.e.,  $T_3 = 13$ . This requires order of  $10^6$  calculations approximately. Whereas to carry out the same analysis for  $n = 4$ , requires much more computational power (at least order of  $10^9$  calculations), therefore we computed only for  $n = 3$ . Also, for  $n = 3$  we are able to obtain a vast spectrum of BN necessary to study our theorem.

The 46656 BN can be divided into: 1728 *XOR* type (i.e., the functions over all its nodes are *XOR* or *XOR*  $\oplus$  1) and 44928 non *XOR* type. Also, from the 46656 BN, 33023 BN have at least one updating mode that produces at least one limit cycle (that can be either constant or non-constant). The remaining 13633 BN have only fixed points for any updating mode.

The 33023 BN can be divided into 1647 that are *XOR* type and 31376 non *XOR* type. They can also be divided in 15443 BN that have at least one updating mode that produces at least one non-constant limit cycle, the remaining 17580 BN never have non-constant limit cycles.

From the 15443 BN, 1275 are *XOR* type, and the remaining 14168 are non *XOR* type.

From the 1275 BN, 1227 share at least one non-constant limit cycle. From the 14168 BN, 10208 share at least one non-constant limit cycle.

Finally, we conclude that  $1227 + 10208 = 11435$ , which represent approximately 25% of the total, is the amount of BN that, regardless if they are *XOR* or non *XOR* type, share at least one non-constant limit cycle.

A summary of these results are shown in Fig. 6.

## Conclusion

In this paper we have characterized digraphs of low connectivity (indegree  $\leq 2$ ) and local Boolean functions (*XOR* or *EQUIVALENCE*) such that a relevant (actually, an exponential number) set of different updating modes do not share non constant limit cycles. Furthermore, the updating modes that can be compared according to the hypotheses of Theorem 1, conform a set that, in the restricted case of strong connectivity (Corollary 1), includes the particular cases of the parallel and serial updates studied in Goles and Salinas (2008) for Boolean networks with monotonic loops. In this context, taking into account our results and the ones obtained in Goles and Salinas (2008), we conclude that unshared limit cycles between the parallel and sequential updating modes occur in at least two situations: when the loops, if they exist, are positive canalizing or when all the local functions are in the *XOR* family  $\mathcal{F}$ .

Finally, the results presented in this paper using *XOR* functions, confirm their importance in the dynamical behavior of Boolean networks, a fact that was recently highlighted in Noual et al. (2012). In addition, our results use sharp hypotheses in the sense that we can exhibit counterexamples in every case where any of these hypotheses do not hold.

# Using Reproductive Altruism to Evolve Multicellularity in Digital Organisms

Jack Hessel and Sherri Goings

Carleton College, Northfield, Minnesota 55057  
sgoings@carleton.edu

## Abstract

The processes by which multicellular organisms first emerged from their unicellular ancestors are fundamental to the biology of complex, differentiated life forms. Previous work suggests that reproductive division of labor between specialized germ and soma cells was central to this evolution in some cases. Here, we assess the potential of the digital life platform Avida to examine the trade-off between survival and replication in multicellular organisms. Avida uses a grid of self-replicating computer programs capable of mutation and evolution to address biological questions computationally. We model our digital organisms after the Volvocales, a flagellated order of photosynthetic green algae that includes both unicellular and multicellular species. We show that, given selective pressures similar to those experienced by the Volvocales in nature, digital organisms are capable of evolving multicellularity within the Avida platform. The strategies we observed that best handled the trade-off between survival and replication involved germ cells producing sterile, somatic offspring. These strategies are similar to those observed in volvocine algae, which suggests that digital platforms, such as Avida, are appropriate to use in the study of reproductive altruism.

## Introduction

How and why multicellular organisms developed are central questions in developmental biology. In life's history, multicellularity has emerged from unicellularity on at least 25 separate occasions (Grosberg and Strathmann, 2007). The fact that this type of specialization and cooperation between cells has emerged independently and repeatedly in organisms ranging from algae to fungi suggests that this phenomenon is not a statistically unlikely event, but is the result of selective pressures experienced by various types of life. Previous theoretical and experimental work has shown multicellularity to be selectively advantageous in several circumstances (Rokas, 2008). In *Chlorella vulgaris*, for example, multicellular forms have evolved from their unicellular counterparts in the presence of a predator within 100 generations, suggesting that a multicellular existence might be advantageous to combat predation (Boraas et al., 1998). Here, we focus on the potential benefits of reproductive division of labor in multicellular forms.

Both reproduction and survival are vital for life to propagate. Differentiation between reproductive germ cells and purely functional soma cells is observed in the Volvocales, a flagellated order of photosynthetic green algae (Kirk, 2001). We chose to model our experimental parameters after the Volvocales specifically because they include multicellular organisms of varying colony size, each of which displays a different degree of complexity and specialization (Koufopanou, 1994).

The primary trade-off Volvocales address is between mobility and reproduction. An algae colony's ability to photosynthesize effectively is dependent upon its depth within the water column, and vertical traversals of entire colonies are common (Sommer and Gliwicz, 1986). A colony's capacity for mobility is primarily determined by the total functionality of its members' flagella.

In the Volvocales, however, cell division damages flagella. When a cell replicates, its flagella continue to function, but "not as strongly or as well coordinated as when [a cell is] not dividing" (Marchant, 1977). After a cell replicates several times its flagella become completely nonfunctional. The number of divisions until a cell loses all flagellar function is generally assumed to be about five (Koufopanou, 1994; Michod et al., 2006). Previous literature suggests that differentiation between germ and soma "may have evolved as a solution to this problem: by denying reproduction to some cells, a parental colony can maintain functional flagella on these cells, which will enable it to maintain its position in the water column while the rest of its cells are dividing" (Koufopanou, 1994). We refer to this constraint as the flagellation constraint.

Another consideration regards the physical volume of germ cells. Reproductive cells in differentiated volvocine colonies tend to have much greater volume than their sterile counterparts (Figure 1). This size differential results from the fact that post-embryonic cell division is not possible (Michod et al., 2006). For the purposes of designing our Volvocale-inspired digital organisms, however, establishing an association between physical volume and replication is adequate. When a colony's total volume increases, its mobil-

Figure 1: *Volvox*, a species of the Volvocales, exhibiting full germ-soma differentiation. The larger cells within the colony are germ cells, while the smaller cells are soma. Image courtesy Frank Fox of [www.mikro-foto.de](http://www.mikro-foto.de).

ity decreases because of increased mass and drag, and more total flagellation is required for colonial motion. Previous work suggests that overcoming this enlargement constraint is yet another benefit to germ-soma specialization (Michod et al., 2006).

It has been shown that reproductive altruism, cells voluntarily producing sterile, somatic offspring for the benefit of their kin, emerges in volvocine green algae. This process involves the expression of an altruistic gene within the parental cell in response to environmental cues (Nedelcu and Michod, 2006; Michod et al., 2006). We aim to implement the enlargement and flagellation constraints in a digital life platform and compare the strategies evolved by digital organisms to those evolved by the Volvocales in nature. While our model could be improved upon, our primary goal is to assess the potential of a digital life platform to address questions of reproductive altruism.

### The Avida Platform

Avida is a software platform that maintains a grid of self-replicating and mutating computer programs, and can be used to address biological questions computationally. Unlike the slow progress of organic evolution, digital evolution allows researchers to conduct experiments relatively quickly; tens of thousands of generations can be executed in a single day. Additional benefits of using a digital platform like Avida include the ability to repeat experiments exactly, specify all environmental parameters, and measure population statistics with precision. Avida is not meant to perfectly model any specific biological system, but supports the basic evolutionary processes of “replication, variation, and differential fitness.” These three conditions create an environment in which evolution will occur (Dennett, 2002). It’s

also worth noting that experimentation within Avida is “not a simulation of a particular evolutionary theory but ... an experimental study in its own right” (Ofria and Wilke, 2004).

The function of a digital organism in Avida is specified by a sequence of low-level computer instructions, in the same way that a genome composed of DNA encodes the form and behavior of a biological organism. The default Avida genomic language contains instructions that perform logical and mathematical operations, functions specific to replication such as allocating and copying memory, and flow control commands that modify the execution order of an individual’s genome. The control commands include instructions that cause small modifications to execution order such as `IF-LESS`, which may skip the immediately following instruction based on a numerical comparison between stored values, and instructions that allow for larger changes such as `MOV-HEAD`, which could cause execution to jump to an instruction anywhere in the genome.

Each Avida organism runs on its own unique set of simulated hardware, including a virtual CPU, three registers, two stacks, input/output functionality, and memory. An organism is allocated memory to hold its own genome of instructions plus extra initially “blank” memory it can use to store the genome of any child it produces. The virtual CPU executes the genome as a continuous sequence of instructions, simply starting again with the first instruction after executing the last. This hardware combined with the instructions in the default Avida language is Turing complete.

In the past, Avida has been used to examine fundamental evolutionary principles in great detail. Notable examples include an examination of the origin of complex features in biological organisms (Lenski et al., 2003) and a study of the relationship between genomic complexity and robustness (Lenski et al., 1999). Because of Avida’s demonstrated capacity to improve our understanding of evolution in general, we believe it is a worthwhile endeavor to assess its potential to address questions of reproductive altruism.

Avida in particular is well suited for our experiments because we are interested in the specific strategies digital organisms might evolve to address the flagellation and enlargement constraints. While a mathematical model or a less complex evolutionary algorithm could offer some insight and might be easier to analyze, it likely would not yield the same depth of information. Some of the more interesting strategies we observed, for instance, would not have appeared in a simpler system.

### Avidian Life-cycle

The Avida life cycle is defined as follows. First, an organism generally executes a sequence of instructions that allocates memory for its child within its own memory space, and copies each of its instructions into this newly allocated memory. Replication is asexual, and occurs when an individual executes an `H-DIVIDE` command, creating a new organism

Figure 2: Avida population partitioned into demes of size 25 and an illustration of a subset of the simulated hardware

from the genome in the child memory space. The parent is reverted to its initial state with blank child memory, and begins execution again with its first instruction. In Avida several instructions in a relatively precise arrangement are required for an organism to replicate, and it is standard to seed starting populations with organisms that already have a hand-coded replication loop in their genomes. However, these instructions are subject to the same mutations and copy errors as the rest of the genome, and organisms frequently evolve modified methods of replication.

Mutation is accomplished through probabilistic instruction addition, deletion and modification within a child's genome prior to its insertion into the greater population. When an organism is copying its instructions into the memory it has allocated for its child, for instance, there is a user-defined probability that the instruction it is attempting to copy will be replaced with a random instruction from the valid set. Avida mutation rates are generally much higher than those found in the natural world; around one mutation on average per child genome is standard.

Organism death occurs either through old-age, or when an organism is overwritten by another's child. All organisms are allowed to execute the same number of instructions on average per update, though the allocation of cpu cycles is stochastic. Therefore organisms that successfully copy themselves using fewer total instructions than average generally have a higher relative fitness. However just as in the nature, many other factors affect a genome's long-term success, such as its robustness to the relatively high mutation rate.

### Multicellularity and Digital Platforms

The origins of multicellularity have previously been investigated in several contexts using artificial life models. Furu-sawa and Kaneko (1998) used an artificial chemistry model to examine multicellular emergence on a simulated two-dimensional grid. Their focus was largely on exploring the

mechanisms that cause cell differentiation during development. Other researchers have studied task-related division of labor, wherein individuals cells cooperate to perform specialized tasks efficiently, as a mechanism by which multicellularity can arise (Michod, 2007). Goldsby et al. (2010) investigated task-related division of labor within the Avida platform and found that digital organisms are capable of selecting specialized roles in groups using both spatial information and inter-organism communication.

In this paper we focus solely on the potential benefits of *reproductive*, as oppose to task-related, division of labor.

Finally, Schlessinger et al. (2006) provided an excellent investigation into the emergence of multicellularity in which they extended the Mosaic World software system to allow for optional organism aggregation into multicellular units. While the authors do include the ability for organisms to forfeit their reproductive capacity, individuals that join a multicellular unit lose their autonomy entirely, as tasks carried out by an aggregation are decided "democratically" through a poll of all constituents. Our investigation, in this context, is orthogonal, utilizing forced aggregation and optional autonomy.

### Extensions to the Avida Platform

We extend the Avida platform to incorporate flagellation and enlargement constraints similar to those exhibited by the *Volvocales* by adding two variables to each digital organism, the *flagella* value and the *physicalSize* value.

*flagella* is a numerical variable that takes on values between  $[0, 1]$ . This variable represents the functionality of a cell's flagella. When a new cell is created, we assume that its flagella are fully functional, and assign it a *flagella* of 1. If and when a cell executes a divide command, we model the flagellation constraint by decreasing this value. We decrease a cell's *flagella* value either linearly, by subtracting .25 upon replication, or exponentially, by dividing by 2 upon replication, depending on the specific experiment.

To model the enlargement constraint, we use the *physicalSize* variable, which represents the physical volume of a cell. While many species of volvocine algae replicate through a more complex process known as palintomy (Michod et al., 2006), we found a simpler binary fission model to be acceptable for our organisms.

In accordance with our binary fission model, we increment a cell's *physicalSize* value each time it executes a copy command such that *physicalSize* increases linearly from 1 to 2, until the parent has copied its entire genome to the child. Upon division, this value is reset to 1.

Because our experiments dealt with cooperation, we were particularly interested in the fitness and replication of groups of cells. The *Volvocales* ultimately specialize and become multicellular forms, so it was necessary to implement multilevel selection and evaluate groups of organisms in addition to individual organisms. We utilized Avida's population partitioning functionality to group organisms into distinct and separate subpopulations, called demes. In our experiments, each deme represented a potential multicellular organism. To evaluate and replicate demes, we modified Avida's *CompeteDemes* framework to accommodate for user-defined deme-level fitness functions and *Volvocales*-inspired deme replication.

Our *CompeteDemes* implementation computes the fitness of each deme semi-periodically and executes a fitness proportional tournament selection with five demes per tournament to determine the next generation of colonies. The timing of each *CompeteDemes* execution is offset by a random value from a uniform distribution. We implemented this deviation because, in early testing, organisms evolved an understanding of perfectly periodic timing and commonly developed undesirable behaviors.

While colonial algal reproduction is considerably more complex, we base our replication implementation on the concept that, in germ-soma differentiated species, all cells in a colony are closely related, and usually derived from the same original germ cell (Michod et al., 2006; Kochert, 1975). To replicate a colony, we select the organisms with the smallest and largest *physicalSize* values, and designate them as the founders of the appropriate demes in the next colonial generation. The cell with largest *physicalSize* is likely in mid-replication during selection, while the cell with the smallest *physicalSize* is likely not replicating during selection. By selecting the physically largest and smallest organisms, we aim to allow a single germ and a single soma cell to found colonies in the next generation, if their parental colony were germ-soma differentiated. While this process differs slightly from naturally observed reproductive mechanisms, our goal was to mimic the selective pressures experienced by *Volvocine* algae, not create a perfect model of their biology.

## Experimental Design

For our experiments, we used a population of 400 demes, each of which contained a maximum of 25 organisms. Real CPU cycles were assigned to each deme according to their living population size, and then randomly to members of that deme.

The unit of time in Avida is the "update," in which an average organism executes 30 instructions. Our experiments were run for  $10^5$  "updates," and terminated after about 10 hours. The initial seed organism executed 390 instructions before reproducing, which translates to an average of 13 updates per generation. The number of instructions executed before reproduction varied considerably between populations, as well as over time and between organisms in a single population, however all values fell within the range [200, 2000].

We designed our fitness function to reward greater total deme flagellar function, and penalize greater deme physical size. With this objective in mind, we decided to limit the space of potential fitness functions to linear combinations of these two deme-level statistics. While this limitation is somewhat arbitrary, our goal was not to perfectly model *Volvocales* colonial fitness, and the following simple, linear trade-off function worked as well as, or better than, any other in evolving populations with interesting, diverse germ-soma differentiated strategies.

$$F = \max(0, \sum \text{flagella} - \frac{\sum \text{physicalSize}}{2})$$

We also implemented a floor on the minimum number of living cells a deme could contain and still be considered viable. We assign a fitness of 0 to demes with less than 15 cells.

Mutation rates were kept at the default Avida settings; for a given command being copied, there was a .75% chance of random instruction replacement. The expected number of mutations depends upon the genomic length of an individual. For a default organism with length 100, for instance, we would expect .75 swap mutations. Additionally, for a single replication event, there was 5% chance that an instruction would be added or deleted from the child's genome upon cell division.

## Results

Before discussing the specific mechanisms digital organisms developed to accomplish germ-soma differentiation, we aim to establish that producing sterile organisms is, in general, a solution to the flagellation and enlargement constraints. We compare the final dominant deme fitnesses from our 46 exponential flagella decay trials to the proportion of somatic cells in the final population for each trial. We find a positive correlation between these variables (Figure 3). This positive correlation indicates that, in general, populations that display higher degrees of germ-soma differentiation produce more fit dominant demes.

Figure 3: Least squares regression of deme fitnesses versus somatic proportion in exponential trials

Figure 4: Average dominant deme fitness over time with bootstrapped 95% confidence intervals using  $10^5$  re-samples

Using an order statistic such as dominant deme fitness in this analysis is appropriate because our fitness function is truncated at 0; the distributions of deme fitnesses are non-normal because of this truncation. A mean, in this case, would not be an accurate reflection of overall population performance.

### Strategic Analysis

Within the exponential flagellar decay experiments, organisms evolved several different strategies, some of which resulted in germ-soma differentiation. Here, we will present these strategies in decreasing order of observed frequency. First, however, it's worth noting that within a single Avida trial, we observed some cases where multiple strategies co-existed. In these trials, it was usually the case that the deme with the highest fitness utilized one of the more complex and

interesting strategies we present here, while the most common replicator in the entire population did not.

Most commonly, no complex, germ-soma differentiated strategy emerged at all. In about 70% of our trials neither the most common nor the dominant replicator utilized a strategy other than adjusting its gestation time and genomic sensitivity to mutation, or "brittleness." The concept and prevalence of brittleness will be addressed in a later section.

The most common germ-soma differentiated strategy, which produced the dominant deme in about 13% of our trials was probabilistic replication. Organisms using this strategy produced children that were accurate copies of themselves a fixed proportion of the time. Probabilistic replicators exhibit phenotypic plasticity, which is the ability to change one's phenotype in response to environmental cues. The Avida platform inputs random numbers to cells to simulate changing environmental conditions. These inputs can be stored and operated on by organisms, if they evolve such behavior. In this case, organisms used these random numbers to determine whether or not to replicate. Those that did not replicate were basically somatic cells in the colony, with the maximum flagella value and minimum physical size. Thus the colony as a whole gained the benefits of germ-soma cell specialization though all constituent cells had identical genomes.

We also observed more complex manifestations of probabilistic replication. In one trial, for instance, a cell replicated with a probability of about 64% but did not always attempt to make an exact copy. Very rarely, this organism produced a purely somatic cell with a separate genotype. The probability of this occurrence was too low to estimate accurately, as a population of several thousand parental cells was required to observe tens of these somatic cells.

The other most common germ-soma differentiated strategy we observed involved parental organisms deterministically producing a tiered set of offspring. For example, in one of our trials, a replicative organism deterministically produced a second, different organism, and this new organism produced sterile offspring. The observed frequency of this behavior in our sample of trials was exactly the same as the probabilistic replicator.

Tiered sets of size three and four were observed, each of which contained exactly one somatic genotype and two or three germatic genotypes, all with similar gestation times. Inherently, these tiered replicative structures encode an expected proportion of sterile cells at the time of deme replication. While the best deme produced by either of these tiered strategies was produced by a three-tiered cell, the proportion of nonviable demes within the three-tiered trial was greater than the proportion of nonviable demes within the four-tiered trial ( $p < .05$ , Student's t-test) indicating that the four-tiered strategy might be more stable.

Of note was one of our trials that could be considered both a tiered and a probabilistic replicator. This particular indi-

vidual produced a tiered set of offspring, where each tier had a statistically unique, associated replicative probability that ranged from about 15% to about 25%.

The least common multicellular strategy that emerged involved cells producing both exact, germatic copies and sterile, somatic cells in deterministic sequences. This behavior was only observed in about 4% of trials. An example of an observed sequence-replicator was a cell that always produced exactly one soma before attempting to replicate itself indefinitely. We also observed genomes that encoded more complex sequences; another cell first produced a single soma, followed by a repeating sequence of one copy of itself followed by two somatic cells.

Because each of these strategies could manifest in an infinite number of ways, however, constructing a definitive ranking of strategic superiority from our data is impossible. We argue that it is only appropriate to compare the ultimate effectiveness of specific strategic manifestations, rather than the strategies themselves.

It is clear, however, that strategies which emerged in trials where selection was applied perform better than no strategy at all. When selection is not applied, mean dominant deme fitnesses are consistently lower, according to data collected from 46 trials with selection and 50 trials without selection (Figure 4).

Trials with “no selection” were still subject to some experimental constraints which selected for certain behaviors. In no selection trials, all demes were assigned identical fitnesses, making deme-level tournament selection random. From demes that were randomly selected for replication, two random organisms were selected as founders. The most common behavior that emerged within these trials was decreased gestation time. Organisms replicating increasingly quickly with no respect to the flagellation and enlargement constraints decreased average deme fitness over time.

### Brittleness

Replicative cells within trials where selection was applied also tended to evolve heightened sensitivity to lethal mutations, increasing their genotypic brittleness; germ cells that developed this behavior ultimately increased the proportion of their offspring that were sterile. This behavior was common in successful replicative organisms that did not exhibit any of the germ-soma differentiated strategies.

The Avida platform supports several types of mutation, and it's likely that cells evolved increased brittleness with respect to each. However, measurement of total brittleness is a computationally expensive process; accounting for every possible combination of legal mutations is impossible. Here, for the sake of computational complexity, we restrict our consideration to the most common mutation type: single-swap.

For each locus in a given organism's genome, each instruction within the legal set was swapped in, holding the

Figure 5: Average single-swap mutation brittleness over time in selection and no selection trials with bootstrapped 95% confidence intervals using  $10^5$  re-samples

rest of the genome constant. The resulting genotype was then analyzed for viability, and the fraction of single-swap mutations that rendered an organism sterile was recorded.

Here, we examine the most common replicative genotype in each of our trials and compare the effect of applying Volvocale-inspired selection on average brittleness. Even in trials where multicellular strategies emerged, however, it was usually the case that the most common replicator did not exhibit a germ-soma differentiated strategy. By examining these typically undifferentiated cells, it was our goal to establish that increased brittleness alone commonly emerges as strategy for addressing the flagellation and physical size constraints.

We find that the average brittleness of the most common replicator in trials where we applied selection was always greater than in trials where we did not (Figure 5). The difference is more consistent early in trials, indicating that increased brittleness likely emerges quickly as an “easy” solution to the flagellation and enlargement constraints prior to the emergence of more complex, differentiated strategies.

In general, the brittleness of organisms in Avida tends to increase naturally over time as genome length and organism complexity increase, which accounts for the increased brittleness we observe in the trials with no applied selection.

### Linear versus Exponential Decay

Up to this point in our analysis, we have not addressed our linear decay trials. We observe that implementing linear decay results in less germ-soma differentiation than exponential decay ( $p < .05$ , Student's t-test). Michod et al. (2006) note that a higher initial cost of reproduction yields a larger benefit from soma specialization to population viability. The Volvocales fitness can be represented in general as a multi-objective problem with an indirect relationship between via-

Figure 6: Flagellar function versus number of replications for exponential and linear flagella decay trials.

bility and fecundity, as a cell has limited resources to invest in each. Multi-objective problem theory predicts that if the trade-off between viability and fecundity forms a concave curve, generalists will evolve, while a convex curve will lead to specialists (Deb, 2005). Increasing the initial cost of reproduction pushes that curve to be more convex. In our experiments, an exponential decay of flagella yielded a much higher initial cost of reproduction than a linear decay, and thus more often led to the evolution of specialists (Figure 6).

## Conclusions and Future Work

We have shown that digital organisms are capable of evolving multicellularity as a solution to the flagellation and enlargement constraints within the Avida platform. The wide range of effective strategies involving germ-soma specialization we observed indicates that digital platforms can be appropriate for studying reproductive altruism. Avida, specifically, was well suited for our experiments because it offered detailed insight into novel strategies digital organisms might use to accomplish germ-soma differentiation.

In the future, we aim to improve upon our model in several ways. For example, in the Volvocales, inter-deme competition is negligible because all organisms result from the same germ cell. In our experiments, however, this type of competition exists, particularly prior to differentiation. We believe that inter-deme competition in Avida could be eliminated by implementing a more dynamic, less periodic deme replication. For instance, a deme could replicate when it contains a given number of cells, rather than at a specific time.

Another potential experimental extension would be to incorporate more physically-inspired parameters into our models. Our deme-level fitness function, for instance, might be better informed by a more careful consideration of the interplay between cell radius, volume and drag. Such consid-

erations would likely not alter our core findings, but might produce new types of organism behavior.

Finally, previous work suggests that, as colonial size increases, multicellularity becomes more advantageous (Michod et al., 2006). This theoretical result is supported by biological observation. In *Volvox*, a multicellular species of the Volvocales, colonies can contain thousands of cells (Kirk, 1998). Allowing for greater colonial size would increase the computation time required for our experiments, but would likely result in a higher proportion of trials evolving multicellularity.

### Abstract

We present work towards clarifying whether and how the idea of agents as “subsystems” of an underlying (artificial) universe can be captured formally. For this we propose formal notions of a universe, a decomposition into subsystems and a criterion to prefer some choices of such decompositions over others. Universes are modelled by finite Markov chains, a decomposition is an information conserving set of subprocesses induced by partitions of the state space and our criterion prefers decompositions that improve predictability by minimizing stochastic interaction. Using very simple examples we find three different classes of Markov chains, with respect to their “decomposability”. Our approach also highlights the fact that the stochastic interaction of multivariate finite Markov chains crucially depends on the chosen multivariate structure of the state space.

### Introduction

#### Motivation

In this publication we address two problems, how to describe a given system as a composition of subsystems (in this paper, only two), and how to pick suitable descriptions among the possible ones. Note, when we say subsystems, we use this term at first in an intuitive way, without having a rigorous definition. Furthermore, we will use “decomposition” and “description” interchangeably as a shorthand when referring to a description as a composition of two subsystems.

The individual subsystems induced by a description should be suitable to represent both agents and environments. Here the agent and its environment could be from biological systems, robots or virtual creatures. This means the class of original systems and the subsystems themselves must be general enough to at least model these three scenarios. Additionally each description should conserve all information about the original system.

Concerning the criterion used to pick descriptions we are eventually seeking one that checks whether the two subsystems can be seen as an agent-environment pair (in other words, form a perception-action loop) and not just a pair of arbitrary subsystems. Note that such a criterion would have to be able to detect agency in the subsystems. We leave

this problem to future work. Here we are satisfied with a weaker criterion, one that can be interpreted to measure the “twoness” of the decomposition. Several concepts can be interpreted in this way: a first candidate would be the independence of the two subsystems from each other; a second related but not necessarily identical concept would be the self-determinedness or autonomy of the individual subsystems; a third would be an increase in simplicity of some kind achievable by a decomposition.

There are two scenarios where describing a system as a composition of subsystems is of interest and our approach might be applied in the future. In the first, take the perspective of an external observer of an artificial universe (e.g. a cellular automaton like the game of life). There is to our knowledge no established way to define subsystems which represent interesting entities/objects (say gliders). In artificial life the interesting entities are those that are the most life-like. The subsystems we seek should be able to represent those and the criterion we seek should pick them out. In the second scenario, take the perspective of an agent subject to a sensor input stream. If indeed decomposing the input stream makes it simpler to process, the agent could benefit from this. Additionally, it has been argued (Salge and Polani, 2011) that detecting other agents has merits in its own right. Roughly speaking, other agents produce more information relevant to an agent than is available in other parts of the environment. This suggests, that in a very general way it is advantageous for an agent to view its sensory input stream as being composed of subsystems, some agents and one environment.

#### Related work

Our work is strongly influenced by Kolchinsky and Rocha (2011). They investigate how learning a model of some given system (a multivariate Markov chain) can be improved by modeling it as a composition of independent subsystems (also Markov chains). In case of a low number of samples to learn from, they find that indeed the predictive error of the model is lowest for a composite model. Their approach is especially convincing in the scenario of an agent subject to an

input stream; the agent modeling the stream as a composite system gaining predictive power in comparison to modeling it as a non-composite one. So in this sense decomposition simplifies prediction for the agent. Note that they vary the compositions of models that are being learned not the descriptions of the original system itself. As we will see the same predictive error can also serve as a useful criterion in the latter case.

Another approach is taken by Balduzzi (2011). He tries to detect emergent subsystems (stochastic processes in general) in a given system (also a multivariate stochastic process, the game of life is used as an example). Here, the subsystems are not chosen once and stay fixed over time, but are composed out of different “units” (groups of variables) at different timesteps and can even skip timesteps altogether. The criterion used to select good choices of subsystems is dependent on how much information (in a specific sense) the different units convey about each other. While this criterion is related to how predictive one unit is of another, this work is not easily comparable with the present one. It is related mainly through the perspective of viewing subsystems as phenomena of an underlying system. This view is also applied specifically to the glider in the games of life by Beer (2013). This is an in depth study of an interesting example of a subsystem in a larger system but up to now the method depends strongly on a preidentified structure.

The system (univariate Markov chain) and subsystems (induced subprocesses) defined by Görnerup and Jacobi (2008) are also used by us. The subsystems are only investigated individually though and compositions that conserve information about the original system are not considered. As a criterion for choosing subsystems the Markov property is used. The Markov property can be interpreted as measuring self-determinedness. We will also employ it but instead of looking directly for Markovian subprocesses we focus on properties of the composition of the subsystems.

One of the authors has previously proposed emergent descriptions (Polani, 2004). Given a stochastic process, emergent descriptions are a set of stochastic processes that contain all information about the original process, are mutually independent and apart from a single one are information conserving. The subsystems we propose here necessarily fulfill the first requirement and a dynamic version of the second one; the third one is not taken into account here.

Once a system has been decomposed into subsystems there are further measures taking into account the interaction of processes that could be used to quantify the suitability of the decompositions. An example employing a framework similar to this paper would be the autonomy measures by Bertschinger et al. (2008).

## Methods

### System

As an extremely simple model for the original system we assume we are given a stationary finite univariate Markov chain<sup>1</sup>  $\{X_t\}_{t \in I}$  (we also refer to it as the universe process) defined by the transition kernel (or Markov matrix)

$$p(x'|x) := p_{x,x'} := Pr(X_{t+1} = x_{t+1} | X_t = x_t) \quad (1)$$

as the right hand side is independent of  $t$  in the stationary case. Our assumption is that the universe process should be Markov, as there is nothing external influencing it and therefore also nothing external to store information about past states in. In the case of the agent facing an input stream this assumption is of course a crude approximation. Choosing finiteness and time discreteness is done for the great reduction of technical issues compared to more general frameworks. Importantly, stationarity may be seen as an approximation, as different choices of subsystems may be most suitable at different times. We choose a univariate process because multivariate processes pre-impose a compositional structure. Moreover, in the finite case each of the variables of the multivariate process takes values in a finite state space; such a process can always be transformed into a univariate process.

### Decomposition via coordinatizations

The decompositions we propose describe the original process via a composition of processes induced on partitions of the state space. The subsystems are then those induced processes. To ensure that the original process  $\{X_t\}_{t \in I}$  can be retrieved from the subprocesses  $\{A_t\}_{t \in I}, \{B_t\}_{t \in I}$  we choose the partitions (we abuse notation and also call them  $A, B$ ) such that they form Cartesian coordinates of the state space  $\mathcal{X} = A \times B$ .<sup>2</sup> For each choice of two such partitions  $A, B$  we then have a bijective map  $f_{(A,B)} : \mathcal{X} \rightarrow A \times B$ . This map is obtained as follows, denote by  $f_A(x) : \mathcal{X} \rightarrow A$  the function mapping  $x$  to the element  $a$  (also called a *block*) of the partition  $A$  that it belongs to, and analogously for  $B$ . Then define

$$f_{(A,B)}(x) := (f_A(x), f_B(x)) = (a, b). \quad (2)$$

It is easy to see that the inverse is equal to the intersection of the blocks  $a$  and  $b$ , which is a unique state  $x$  in this case:

$$f_{(A,B)}^{-1}(a, b) := \{x : x \in a \cap b\}. \quad (3)$$

<sup>1</sup>Either we choose the index set  $I$  as the integers or we initialize the process in its stationary distribution at some time  $t = t_0$  and let it run indefinitely.

<sup>2</sup>This condition ensures for the purpose of this paper the more general requirement, that the subprocesses lose no information about the original process, i.e.  $H(X_t | A_t, B_t) = 0$  at all times  $t$ , where  $H$  denotes the Shannon entropy.

The fact that  $\mathcal{X} = A \times B$  ensures that there is always exactly one  $x$  in this intersection. For the rest of this paper we will refer to such a pair of partitions as a *coordinatization*.

In this way we obtain an alternative description of the original process  $\{X_t\}_{t \in I}$  and can set:

$$p(a', b' | a, b) := p(f_{(A,B)}^{-1}(a', b') | f_{(A,B)}^{-1}(a, b)). \quad (4)$$

Note that in general the induced subprocesses interact with each other, so that we obtain two interacting stochastic processes. This seems suitable for representing an agent-environment pair which was one of our requirements. At least it is not uncommon to model such interaction in this way; often in the context of perception-action loops (Klyubin et al., 2004; Bertschinger et al., 2008; Ay et al., 2012).

To generate coordinatizations, we note that each map  $f_{(A,B)}$  can be visualized as a way of filling an  $|A| \times |B|$  grid with the states of  $\mathcal{X}$ . We will call this grid the *coordinatization grid*. Then rows correspond to the blocks of  $A$  and columns correspond to the blocks of  $B$ . For example, if  $f_{(A,B)}(x) = (a, b)$ , the state  $x$  will appear in the grid at the intersection of row  $a$  and column  $b$ . Each coordinatization then corresponds to coordinatization grid and vice versa.

We note though that if we rename the blocks in  $A$  ( $B$ ) this has no influence on the properties of the process induced on  $A$  ( $B$ ) or on the partitions they represent. Renaming the blocks in  $A$  ( $B$ ) corresponds to permuting rows (columns) in the coordinatization grid. We therefore can reduce the number of coordinatizations that we have to investigate by choosing only one of each set of coordinatizations that can be obtained via row or column permutations of their associated grids. This can be achieved for example by always mapping state  $x = 1$  to the top left corner; mapping states to the top row such that their values are increasing to the right; and to the leftmost column such that their values are increasing downwards. Instead of  $|\mathcal{X}|!$  ways of mapping the states to the grid (and a resulting  $|\mathcal{X}|!$  coordinatizations) there are only  $|\mathcal{X}|/|A|!|B|!$  possibilities of this kind. This is still too big a number to check for larger systems, but we can already obtain some interesting insights from analysing small ones.

### Coordinatizations and modularizations

Coordinatization of a univariate process as defined above results in a bivariate process. The method could easily be extended in order to obtain multivariate processes with 3, 4, 5... subprocesses by using 3, 4, 5, ...-dimensional coordinatization grids. In this sense any finite multivariate process is already a generalized coordinatization of some underlying univariate finite process. Given a multivariate process of  $k$  variables it is possible to combine multiple of those variables (e.g. the first few in one group the rest in another) in order to get a bivariate process i.e. a coordinatization (this is a case of what Kolchinsky and Rocha (2011) call modularization). We want to stress that by combining variables

of a multivariate process i.e. by modularization, not all possible coordinatizations can be obtained. Only if the process is viewed as univariate and the coordinatizations are constructed from there, all possible ones are obtained. In other words modularizations result in only a subset of the possible compositional structures. This can be seen when considering a bivariate process as given, combining variables further is then not possible anymore, so only one coordinatization (the given one) can be obtained by modularization. Yet if the process is defined on state space  $\mathcal{X}$  and any given structure is ignored, there are  $|\mathcal{X}|!/u!v!$  possible ways of mapping the states in  $\mathcal{X}$  into a  $u \times v$  coordinatization grid and as many coordinatizations for each pair  $u, v$  of factors of  $|\mathcal{X}|$ .

### Criterion

To choose the most suitable among the coordinatizations we calculate the *stochastic interaction* (Ay and Wennekers, 2003)  $I_{(A,B)}$  (Eq. 5 below) with respect to the coordinatization  $(A, B)$  and look for those that minimize it. This can be motivated for both scenarios, the external observer and the agent perspective.

In case of the external observer, note that stochastic interaction measures in a specific sense in how far the system dynamics is more than a composition of independent subprocesses. Conversely, a low stochastic interaction indicates the composition of independent subprocesses. For a coordinatization a low stochastic interaction can then be interpreted as a measure of “twoness”.

Next take the perspective of an agent, who assumes that its input process is a composition of independent subprocesses and models it as such. If the predictive error can be reduced by this assumption the agent would have a good reason to make it. As Kolchinsky and Rocha (2011) have argued, the predictive error of a model is the sum of two terms, the error due to the assumed composition and the error due to imperfection of the learned model. The error due to the assumed composition is quantified by the stochastic interaction and is independent of other features of the learning method or model. The second term of the predictive error (or risk) then quantifies the error due to the imperfection of the parameters of the composite model. This error decreases with the number of samples available to the learner. We do not focus on this second term here but want to find the coordinatization which minimizes the “baseline error” i.e. the stochastic interaction which a possible learned composite model can reach in the best case.

For a bivariate stochastic process like the coordinatizations the stochastic interaction is defined as<sup>3</sup>

$$I_{(A,B)}(X'|X) = \text{KL}[p(A', B'|A, B) || p(A'|A)p(B'|B)] \quad (5)$$

<sup>3</sup>For the general definition we refer reader to Kolchinsky and Rocha (2011) and Ay and Wennekers (2003).

$\text{KL}[\cdot|\cdot]$  denotes the Kullback-Leibler divergence, which is in this case defined as

$$\text{KL}[p(A', B'|A, B) || p(A'|A)p(B'|B)] := \sum_{a,b} p(a,b) \sum_{a',b'} p(a',b'|a,b) \log \frac{p(a',b'|a,b)}{p(a'|a)p(b'|b)}.$$

The marginalised transition kernels  $p(a'|a), p(b'|b)$  are calculated from the transition kernel of the original process and a given starting distribution (e.g. the stationary distribution)  $p(x)$ :

$$p(a'|a) := \frac{\sum_{x': f_A(x')=a', x: f_A(x)=a} p(x'|x)p(x)}{\sum_{x: f_A(x)=a} p(x)}, \quad (6)$$

$$p(b'|b) := \frac{\sum_{x': f_B(x')=b', x: f_B(x)=b} p(x'|x)p(x)}{\sum_{x: f_B(x)=b} p(x)}. \quad (7)$$

### Procedure

The procedure we use for the analysis of the examples below is then the following. We start with a given transition kernel  $p(x'|x)$  (or the according Markov matrix with elements  $p_{x,x'} = p(x'|x)$ ) of a finite Markov chain with state space  $\mathcal{X} = 1, \dots, |\mathcal{X}|$ . Next, we calculate the stationary distribution  $p(x)$  as the left eigenvector  $v$  to the eigenvalue  $\lambda = 1$  of  $(p_{x,x'})$ . We then generate the candidate coordinatizations  $(A, B)$  via the coordinatization grid. Finally, among the coordinatizations obtained in this way, we look (brute force) for the coordinatizations that minimize the stochastic interaction, Eq.5, which represent arguably the most “natural” decompositions of  $\{X_t\}_{t \in I}$  into two subsystems. For those coordinatizations we also check the Markov property for each of the two induced subprocesses  $\{A_t\}_{t \in I}$  and  $\{B_t\}_{t \in I}$ . This can be done by checking that for any blocks  $a, a' \in A$  the total probability  $\sum_{x' \in a'} p(x'|x)$  to transition from any  $x \in a$  to  $a'$  is independent of  $x$  (Kemeny and Snell, 1976).

### Examples

We study the ideas discussed above in a class of simple systems.

Imagine a box (agent) moving on a  $m \times n$  grid wrapped around at the edges. The agent can only move up, down, left, or right (not diagonally), and does so with probability  $1/4$  in each direction at every timestep. This system then has  $mn$  states, so the state space  $\mathcal{X} = \{1, \dots, mn\}$  and every agent position corresponds to a state of the system. To make the explanations more transparent, we fix which position of the agent corresponds to which state  $x$ . Starting with  $x = 1$  in the top left corner, enumerate the top row and continue always from left to right with all other rows (cf. e.g. Fig.1). Note that this can be chosen arbitrarily. All that matters is how these states are mapped to the grid which defines the coordinatization. The latter is an  $|A| \times |B|$  grid, and even though the products  $|A||B| = mn = |\mathcal{X}|$

are necessarily equal,  $|A|, |B|$  can be a pair of factors of  $|\mathcal{X}|$  different from  $m, n$ . For example, let  $m = 3, n = 4$  then  $\mathcal{X} = \{1, \dots, 12\}$  and the tuples  $(|A|, |B|)$  can be any of  $(2, 6), (3, 4), (4, 3), (6, 2)$  where the last two possibilities correspond to substituting  $A$  and  $B$  and will reveal no more than the first two.

We now look at this system for different  $m$  and  $n$ .

**Let  $m = 3$  and  $n = 3$ :** The world grid then looks like this:

|  |  |  |
|--|--|--|
|  |  |  |
|  |  |  |
|  |  |  |

and the state space is  $\mathcal{X} = \{1, \dots, 9\}$ . Because the states of the system are just positions on the grid, as mentioned before we label the positions with the states  $x$  in the way shown in Fig. 1. Just to give an impression, the  $|\mathcal{X}| \times |\mathcal{X}| =$

|   |   |   |
|---|---|---|
| 1 | 2 | 3 |
| 4 | 5 | 6 |
| 7 | 8 | 9 |

Figure 1: World grid labelled with states  $\{1, \dots, 9\}$  in the way mentioned in the text.

$9 \times 9$  Markov matrix  $(p_{x,x'})$  of this system then looks like this

$$(p_{x,x'}) = \begin{pmatrix} 0 & \frac{1}{4} & \frac{1}{4} & \frac{1}{4} & 0 & 0 & \frac{1}{4} & 0 & 0 \\ \frac{1}{4} & 0 & \frac{1}{4} & 0 & \frac{1}{4} & 0 & 0 & \frac{1}{4} & 0 \\ \frac{1}{4} & \frac{1}{4} & 0 & 0 & 0 & \frac{1}{4} & 0 & 0 & \frac{1}{4} \\ \frac{1}{4} & 0 & 0 & 0 & \frac{1}{4} & \frac{1}{4} & \frac{1}{4} & 0 & 0 \\ 0 & \frac{1}{4} & 0 & \frac{1}{4} & 0 & \frac{1}{4} & 0 & \frac{1}{4} & 0 \\ 0 & 0 & \frac{1}{4} & \frac{1}{4} & \frac{1}{4} & 0 & 0 & 0 & \frac{1}{4} \\ \frac{1}{4} & 0 & 0 & \frac{1}{4} & 0 & 0 & 0 & \frac{1}{4} & \frac{1}{4} \\ 0 & \frac{1}{4} & 0 & 0 & \frac{1}{4} & 0 & \frac{1}{4} & 0 & \frac{1}{4} \\ 0 & 0 & \frac{1}{4} & 0 & 0 & \frac{1}{4} & \frac{1}{4} & \frac{1}{4} & 0 \end{pmatrix}. \quad (8)$$

Next, we choose a factor of  $|\mathcal{X}|$  as the cardinality  $|A|$  of the partition  $A$  which will be the number of states of the induced subprocess. This determines also the cardinality of  $B$  as  $|B| = |\mathcal{X}|/|A|$ . In the present case, where  $|\mathcal{X}| = 9$  we

Figure 2: This illustrates the naive coordinatization of the  $3 \times 3$  world. We show the world grid and overlay the coordinatization, the tuples in each grid position denote  $f_{(A,B)}(x) = (f_A(x), f_B(x))$  where  $x$  is the state label fixed to the grid position as described in the text. The left (right) diagram highlights the partition  $A$  ( $B$ ) with each block  $a$  ( $b$ ) given the same color.

can only choose  $|A| = |B| = 3$  as a nontrivial factorization. Thus, the world grid and the coordinatization grid look the same. Before we calculate the natural coordinatization, let us look at a particular candidate coordinatization, which for lack of a better term we call the *naive coordinatization*.

For this, map the states  $x$  into the coordinatization grid in just the same way that we mapped them into the world grid, i.e.  $f_{(A,B)}(x) = (\lfloor x/|B| \rfloor, x \bmod |B|)$ . Then the position of the box on the grid is represented by the tuple  $(a, b)$  where  $a$  denotes the row and  $b$  the column. In Fig.2 we visualize the two partitions  $A$  and  $B$  and also indicate the resulting labelling of the states (and therefore positions) of the box.

One salient feature of this coordinatization is, that the dynamics can be specified easily:

$$p(a', b' | a, b) = \begin{cases} \frac{1}{4} & a' = a \pm 1, b' = b \\ \frac{1}{4} & a' = a, b' = b \pm 1 \\ 0 & \text{else.} \end{cases} \quad (9)$$

Surprisingly, this is not the “natural” coordinatization from our perspective here, its stochastic interaction is  $I_{(A,B)}(X'|X) = 1$ . Yet, there are two coordinatizations that reduce the stochastic interaction  $I_{(A,B)}$  to zero. For both, the two partitions  $A$  and  $B$  are shown in Fig.3. Note that we can transform them into each other by “transposing” the gridlabelling which is due to the fact that we can just exchange  $A$  and  $B$ . To get an intuition for the solutions which let the stochastic interaction vanish, note that instead of rows and columns, now the blocks divide the world grid into its diagonals. We also found that the induced processes of each of those coordinatizations are Markov.

**Let  $m = 2$  and  $n = 4$ :** Choose  $|A| = 2$  so that  $|B| = 4$ . Similarly to the  $3 \times 3$  world, the naive coordinatization leads to a stochastic interaction of  $I_{(A,B)}(X'|X) = 1$  and we find 6 different coordinatizations for which it vanishes. In all of the later, partition  $A$  consists of the blocks formed by the two diagonals “winding around” the world grid (at least they can

Figure 3: The two different coordinatizations of the  $3 \times 3$  world process. Each row corresponds to a different coordinatization. Again we highlight partition  $A$  ( $B$ ) in the left (right) diagram and indicate  $f_{(A,B)}(x) = (f_A(x), f_B(x))$  at each grid position. Focussing on the first coordinatization (top row), notice that when the agent is in the central position and goes up or right, the first coordinate (the block of partition  $A$ ) changes from 1 to 2 in both cases, and if it goes down or left it changes from 1 to 3 in both those cases. This means that with probabilities  $p_A(2|1) = p_A(3|1) = 1/4 + 1/4 = 1/2$  the agent switches the  $A$  blocks. Similarly, for upward or leftward movement the  $B$  block changes from 1 to 3 for downward or rightward from 1 to 2, hence  $p_B(2|1) = p_B(3|1) = 1/2$ . Done similarly for all grid positions, we see that this is the same as if we had two independent agents switching between three positions at each timestep.

always be arranged like this via permutation of the columns of the coordinatization grid) see Fig. 4. The blocks of partition  $B$  take a variety of forms. Again all subprocesses are Markov.

**Let  $m = 3$  and  $n = 4$ :** First let us choose  $|A| = 3$  so that  $|B| = 4$ . Again the naive coordinatization gives  $I_{(A,B)}(X'|X) = 1$ . The minimum stochastic interaction is non-zero though, with 6 different coordinatizations reaching a value of  $I_{(A,B)}(X'|X) \approx 0.43$  see Fig. 5. Notice, that partitions which group together diagonals of the world grid are impossible for the  $3 \times 4$  grid, because, as a diagonal winds around the grid it only self intersects after traversing the whole state space, so that there is essentially only one diagonal in each direction. Note also that all partitions  $B$  that are part of the stochastic interaction minimizing coordinatizations do not induce Markov processes, while the partitions  $A$  still do.

Now let us choose  $|A| = 2$  so that  $|B| = 6$  and the world grid and the coordinatization grid are not of the same form anymore. The coordinatizations with minimum stochastic

Figure 4: The coordinatizations minimizing stochastic interaction for the  $2 \times 4$  world process. The subprocesses induced by the agent dynamics on the partitions  $B$  highlighted in the right column are Markov. The same holds for the subprocess induced on the partition  $A$  shown on the left.

interaction achieve a value of  $I_{(A,B)}(X'|X) \approx 0.31$  see Fig. 6, with both  $A$  and  $B$  inducing Markov processes. It can be seen that both coordinatizations use the same patterns to cover the world grid. In fact one can obtain the other by permuting the columns of the world grid. The reason the two coordinatizations are seen as different by our algorithm is that in the coordinatization grid they cannot be transformed into one another (see Fig. 7).

**Let  $m = 2$  and  $n = 3$ :** In this case we can only choose  $|A| = 2$  and  $|B| = 3$  which leads to three different coordinatizations that achieve a minimum stochastic interaction of  $I_{(A,B)}(X'|X) \approx 0.19$ . The process induced on the partitions  $A$  is not Markov in these cases while the process induced on  $B$  is.

### Discussion

Formally, our examples have revealed three different classes of Markov chains. First, processes that allow coordinatiza-

Figure 5: The coordinatizations minimizing stochastic interaction for the  $3 \times 4$  world process with  $|A| = 3$  and  $|B| = 4$ . Here the subprocesses induced by the agent dynamics on the partitions  $B$  highlighted in the right column are not Markov. Those induced on the partitions  $A$  in the left column are.

tions with vanishing stochastic interaction and Markov processes as the two subprocesses. Second, processes for which no coordinatization with vanishing stochastic interaction exists but whose coordinatizations that minimize stochastic interaction induce Markov processes (e.g. the  $3 \times 4$  world with a coordinatization grid of  $2 \times 6$ ). And third, systems where the minimum but non-zero coordinatization contains one subprocess that is not Markov ( $2 \times 3$  world). These results are summed up in the following table (“non-M” stands

Figure 6: The coordinatizations minimizing stochastic interaction for the  $3 \times 4$  world process with  $|A| = 2$  and  $|B| = 6$  which means the coordinatization grid is different from the world grid, see Fig.7. Note that the index pairs  $f_{(A,B)}(x) = (f_A(x), f_B(x))$  reflect the  $2 \times 6$  coordinatization grid. Also note that by switching columns 2 and 4 of the grid in the first row one can obtain the grid in the second row. Also note that the induced processes of all the partitions shown here are Markov.

Figure 7: The coordinatization grid for the two different  $|A| = 2$  and  $|B| = 6$  coordinatizations that minimize stochastic interaction for the  $3 \times 4$  world process. Shown is the way the states  $\mathcal{X} = \{1, \dots, 12\}$  are mapped to the blocks of partitions  $A$  and  $B$ . The rows are the blocks of  $A$  and the columns are the blocks of  $B$ . For example, in the left coordinatization, state  $x = 5$  is mapped to  $(a = 1, b = 3)$ .

for not Markov and “M” for Markov):

| $m \times n$ | $ A  \times  B $ | $I_{(A,B)}^{\min}$ | $\{A_t\}_{t \in I}$ | $\{B_t\}_{t \in I}$ |
|--------------|------------------|--------------------|---------------------|---------------------|
| $2 \times 3$ | $2 \times 3$     | 0.19               | non-M               | M                   |
| $2 \times 4$ | $2 \times 4$     | 0                  | M                   | M                   |

The fact that the stochastic interaction vanishes for some coordinatizations and for some not, shows that the stochastic interaction depends crucially on the chosen coordinatization of a stationary finite Markov chain. Systems that might not seem decomposable, like the agent on the  $3 \times 3$  grid with the naive coordinatization, can in fact still allow clean decompositions like the “diagonal” coordinatization.

On the other hand the processes for which no coordinati-

zation achieves a vanishing stochastic interaction and therefore resist clean decomposition can possibly be seen as fundamentally integrated units. Here comparisons to other measures of integration e.g. Balduzzi and Tononi (2008) suggest themselves and will be pursued in future work.

More generally, our results seem to call for interaction or integration measures that are independent of the coordinatization. A dependence on the chosen cardinalities  $|A|, |B|$  (as in the  $3 \times 4$  world) may still be desirable though.

With respect to the scenario of an external observer, we could show that if an artificial universe (e.g. cellular automata) is formulated in one specific coordinatization (possibly more than two dimensional, e.g. the game of life), this coordinatization might not be the one best suited for decomposing it into subprocesses. Again recall the  $3 \times 3$  world grid; our system has actually been devised in the way of Eq. 9.

As already mentioned, the decomposition into stochastic processes seems, if only through its generality, capable of accommodating agents and environments, but our examples are inconclusive on this matter.

From the perspective of an agent subject to an input stream, it had been known that the assumption of composed processes can help reduce predictive error. Kolchinsky and Rocha (2011) have shown that given a multivariate process, assuming that groups of variables form independent processes can improve model learning. Our examples show that if the multivariate structure of the process is ignored more compositions of subprocesses can be found and might reduce the predictive error further. We can interpret this in the following ways: The multivariate structure might be imposed by the agents sensory apparatus. Then the modularizations of Kolchinsky and Rocha (2011) could be seen as the best an agent can do. From our perspective the multivariate structure is not fixed though. This corresponds to the situation where the sensory apparatus of the agent is not fixed but can still be adapted (e.g. by evolution). A third more speculative interpretation might be that the agent has to “see through” the multivariate structure and actively conceive the stochastic interaction minimizing decomposition to optimize its predictive power.

## Conclusion and outlook

Mathematically, we have proposed an approach for the decomposition of stationary finite Markov chains into pairs of subprocesses which retain all information about the original process, we refer to this as coordinatization. Minimization of stochastic interaction was used to determine “natural” coordinatizations. Three different classes of finite Markov chains showing different kinds of “decomposability” were found in the simple examples treated here.

Importantly, our approach reveals that stochastic interaction depends crucially on the chosen coordinatization. This implies that for a given multivariate Markov chain, con-

structuring coordinatizations that ignore the given multivariate structure might achieve cleaner decompositions than any grouping together of the given variables (modularization) can achieve. Such coordinatizations might in fact reduce stochastic interaction to zero. Since stochastic interaction is a lower bound for the predictive error of composite models (Kolchinsky and Rocha, 2011), our approach can in the best case be used to boost the predictive performance of such models.

In practice though the naive search method for the coordinatizations minimizing the stochastic interaction is computationally unfeasible. It remains to be seen if improved search methods can move the approach into the efficient realm.

From an artificial life perspective, we have argued for a natural choice of decompositions of a system into two subsystems for the large class of finite Markov chains. This choice can reveal ways to view and describe systems which might otherwise be overlooked. In principle the subsystems resulting from our decomposition (interacting stochastic processes) seem suitable to represent an agent and its environment or two interacting agents. Whether our criterion can be used to identify them remains an open question.

In the future we hope to extent our approach so that it can serve artificial life researchers as an analytical tool in the context of agent-environment systems or perception-action loops.

## Abstract

Higher level selection processes such as species selection are not generally predicted to overpower individual selection on character traits. Goldberg et al. provide a model derived from collected life history data and argue that species selection is maintaining self-incompatibility in the Solanaceae plant family. This model applies only on the level of the species, not representing the underlying interactions between individuals and the environment. We propose a new model with environmental variation at the individual level that may explain the maintenance and frequency of loss of this character trait. We use individual based modelling techniques to explore our hypothesis, and compare it with that originally proposed. The results show alternative values required for the mutation rate to produce the species level transition frequency under the opposing models, given certain assumptions. Future work is suggested to refine the parameter relationships, test for robustness, and determine if individual models of higher complexity will exhibit similar outcomes.

## Introduction

Evolutionary questions that address multiple levels of the biological hierarchy offer a particular challenge to researchers. There is lack of consensus among biologists about the level(s) at which Darwinian natural selection should be considered to act (Okasha, 2006). This debate about the levels of selection has a complex history, marked by the group selection controversy (Wilson, 1983; Okasha, 2001), and theories of multi-level selection (Damuth and Heisler, 1988) and inclusive fitness (Hamilton, 1964; Queller, 1992).

Empirical data concerning the life history of individuals and species is in many cases insufficient to answer biological questions conclusively (Johnson and Omland, 2004; Turchin, 2013). Mathematical models have been used extensively, but they cannot capture the complexity of interactions in all cases. Individual based modelling techniques can be used to approach problems of this nature, using computer simulations of interacting systems at multiple levels. These models can expose outcomes of theoretical positions that may not be readily apparent (Di Paolo et al., 2000). Their flexibility and speed additionally allow systematic exploration of parameter spaces, testing the robustness and plau-

sibility of proposed ideas. Their potential for incorporating environmental interaction can be key in exposing the workings of natural systems (Brooks, 1991).

In this paper we model the individual interactions within the species that underlie the model of Goldberg et al. (2010). We consider individual level selection, that is, natural selection competing between individuals within a given species, to try to expose the lower level dynamics that are giving rise to the outcomes seen at the level of species. We compare two alternative formulations with different profiles of environmental interaction; the first assuming that, as proposed by Goldberg et al., species selection is acting in direct opposition to the lower level individual selection; the second introducing environmental variation. Individual level selection processes are generally considered more powerful than their higher level counterparts such as species selection (Lewontin, 1970). Species selection is therefore rarely cited as able to maintain a trait that is disadvantageous to the individual, but this has been suggested in the case of self-incompatibility in the Solanaceae (nightshade) plant family (Goldberg et al., 2010).

In the next section we discuss the evolutionary background of self-incompatibility in the context of Goldberg et al.'s work. We then introduce the theoretical concepts behind the competing evolutionary incentives. Following this, we lay out the mathematical model of fitness that will form the basis of our individual model. With the mathematical framework in place, we describe the details of the computer simulation and the relevant parameters. Finally, we go on to discuss the results.

## Self-Incompatibility and the Goldberg et al. Model

Self-incompatibility (SI) in plants is a mechanism to prevent self-fertilisation and encourage outcrossing – reproduction with those genetically dissimilar; this increases the genetic diversity of offspring (Barrett, 1988). The alternative, however – self-compatibility (SC) – can be immediately evolutionarily advantageous to individuals in SI populations, as self-fertilising (or selfing) allows plants to pass on their

genes with higher probability, and selfing plants need not rely on inbound pollen when it is scarce (Lloyd, 1992; Igic et al., 2008).

Goldberg et al. reconstructed a tree of life for the nightshade family, and found a maximum likelihood model that captures the evolution of the species in the family and their relationship with self-incompatibility and self-compatibility. The model shows that SI species have an average rate of transition to SC of 0.555 per lineage per million years, yet a proportion of SI species continues to survive over evolutionary time. This appears to be because SI species have a higher net rate of growth than SC species. This difference (a species-level advantage) is greater than the rate of transition, allowing a proportion of species to be maintained as SI ongoing, despite regular transition to SC.

In claiming that species selection is maintaining self-incompatibility, Goldberg et al. argue that individual evolutionary incentive for SC is constantly present, but the rate of arrival (and spreading) of the SC mutation in each SI population is sufficiently low to keep the transition rate averaging at this 0.555 per million years figure. This rate is low enough to allow the difference in net species growth (diversification) to be the more significant evolutionary force.

We propose a model where a background factor, a rate of occurrence of temporary environmental disruption, is the cause for a given species transition to SC. Under this model, individual selection does not constantly favour selfing, but is rather selectively neutral, or marginally favouring outcrossing. When the environmental disruption occurs, the relative fitness of selfers increases temporarily, and there is opportunity for an SC mutant to arrive and spread in the population. As long as this model can be shown to achieve the same average transition rate for reasonable sets of parameters, it may offer an alternative explanation for the maintenance of outcrossing that does not require species selection to overpower individual selection unaided.

It is important to note that while transitions from SI to SC are regular and frequent, transitions back to SI are negligibly rare (Igic et al., 2008). This may be due to the complexity of the SI system; it requires genetic coordination at many loci, so there are many points of failure (Franklin-Tong, 2008). There may also be a self-perpetuating dynamic to selfer evolution, as under certain conditions, an increase in the proportion of selfers also increases selfer fitness, making evolution back to SI once a species has been fully invaded by SC particularly improbable.

### Individual Selection Models of Selfing versus Outcrossing

A strong individual incentive for selfing is believed to be its transmission advantage, termed *automatic selection* (Fisher, 1941). Selfers have a 3:2 advantage of gene transmission, as their seeds on average contribute two gametes to the next generation to the outcrosser's one (while both averaging an

additional one through pollen) (Busch and Delph, 2012). This transmission advantage is opposed by inbreeding depression – a generalised concept for the lower average fitness of selfed progeny. Selfed progeny may have lower fitness for a number of reasons, including reduced genetic diversity, and exposition of harmful recessive alleles (Charlesworth and Charlesworth, 1987). In simple models, inbreeding depression is represented by a value  $\delta$  which is the per progeny reduced fitness for a selfed individual. If  $\delta > 0.5$ , the selfer's transmission advantage is outweighed by inbreeding depression, and outcrossing is evolutionarily preferred (Jarne and Charlesworth, 1993): 0.5 is the equilibrium level of inbreeding depression in this model of transmission advantage. This simple relation assumes that selfer pollen is just as successful as outcrosser pollen, ignoring any pollen discounting. Pollen discounting,  $0 \leq p \leq 1$ , is the reduced relative fitness of pollen spores for selfer pollen (Nagylaki, 1976).

Using Lloyd (1992)'s phenotypic model of selfing versus outcrossing, a non-zero level of pollen discounting results in a frequency dependent equilibrium value for inbreeding depression  $\delta$  (Nagylaki, 1976). That is, the maximum level of inbreeding depression required to prevent evolution to selfing varies with the proportion of selfers (explained below with eq. (3)). It can therefore provide a self-perpetuating dynamic to the evolution of selfing, as the level of  $\delta$  required to maintain outcrossing increases with the proportion of selfers, so as more selfers evolve, it becomes increasingly more difficult to maintain outcrossing. This means that if environmental circumstances are temporarily in a state that encourages evolution to SC, the proportion of outcrossers may drop below the level at which outcrossing could be maintained even once the environment returns to its previous state. This is a mechanism by which, without any assumed change in inbreeding depression, a temporary environmental disruption may cause one-way transitions to SC.

Our proposed environmental disruption is a temporary limitation of pollen dispersal in the population. This reduces inbound pollen availability to outcrossing plants by an amount  $0 \leq l \leq 1$ . This limitation also has fitness consequences for selfers, as outbound pollen from selfer plants will be less likely to reach and sire an outcrosser ovule for reproduction. The limitation still has a greater negative effect on outcrossers than selfers, as self-fertilised seeds will be unaffected by the lack of pollen dispersal, while all outcross progeny will be penalised.

### The Mathematical Model of Selfing versus Outcrossing

For general pollen limitation  $l$ , the initial fitness of outcrossers  $W_x$  and selfers  $W_s$  are:

$$W_x = 1 - l \quad (1a)$$

$$W_s = 1 - \delta \quad (1b)$$

This corresponds to inbreeding depression for selfers, and inbound pollen limitation for outcrossers. The transmission advantage also needs to be factored in, for which we adapt the model from (Lloyd, 1992). The transmission advantage is the result of an additional crossover process for outcrossers, in which their offspring have an average 50% chance of transmission of the trait carried by the inbound pollen (rather than their own) (Fisher, 1941). The outcrosser fitness is therefore scaled by  $\frac{1}{2} + \frac{1}{2}m_x$ , where  $m_x$  is the probability the mate is also an outcrosser. The complement of this amount ( $\frac{1}{2} - \frac{1}{2}m_x$ ) is added to the selfer fitness (representing those outcrosser progeny transmitting the selfer phenotype). This term, however, is scaled by the relative proportion of outcrossers to selfers and reduced by pollen limitation, as selfers only benefit as much as there are outcrosser ovules available to sire and their pollen can reach them. The comprehensive fitness equations are therefore:

$$W_x = (1 - l)\frac{1}{2}(1 + m_x) \quad (2a)$$

$$W_s = \frac{x}{1 - x}(1 - l)\frac{1}{2}(1 - m_x) + 1 - \delta \quad (2b)$$

$$\text{where } m_x = \frac{x}{x + (1 - x)(1 - p)} \quad (2c)$$

Again,  $m_x$  is the probability of inbound pollen being outcrosser rather than selfer, incorporating the effect of pollen discounting  $p$ . The current proportion of outcrossers in the population is  $0 \leq x \leq 1$ .

From these fitness equations we derive the level of equilibrium inbreeding depression  $\delta$ , above which outcrossing is evolutionarily preferred, and below which selfing is preferred:

$$\frac{2lp_x + (1 + l)(1 - p)}{2(p(x - 1) + 1)} \quad (3)$$

Refer to figs. 1(a) and 1(b) for an illustration of this relationship. As we can see, for  $0 < p < 1$ , the level of inbreeding depression required to maintain outcrossing increases with selfer proportion (ie. with decreasing  $x$ ); selfers have a greater advantage as the selfer proportion increases. Further, the addition of pollen limitation  $l = 0.2$  in fig. 1(b) shifts the curves upward, giving selfers a selective advantage over the  $l = 0$  condition. The curves are also contracted in the vertical ( $\delta$ ) dimension, making this difference more pronounced at higher levels of  $p$ . We use changes in the value of  $l$  to exhibit temporary environmental conditions that favour selfing.

(a) Equilibrium  $\delta$  without pollen limitation ( $l = 0$ )

(b) Equilibrium  $\delta$  under pollen limitation ( $l = 0.2$ )

Figure 1: Equilibrium inbreeding depression  $\delta$  at outcrosser proportion  $x$  for different values of pollen discounting  $p$ , with 1(b) and without 1(a) pollen limitation  $l$  (see eq. (3)).

We present two alternative models. In the first, Model A, the transition rate is caused exclusively by the arrival and fixation of the selfer mutation, under conditions that constantly favour selfing. In Model B, conditions generally favour outcrossing, but there are environmental disruptions, occurring with a certain rate  $r$ , that limit  $l$  the pollen dispersal for some duration  $d$ , during which the conditions favour selfing. This second model, the environmental model, will require a higher mutation rate than the first, as selfer morphs are only favoured by natural selection during disruptions, rather than constantly. The final point of differentiation for the two models, then, will be the mutation rate required to achieve the empirically observed transition rate, given the

background assumptions of the models.

## Methods

As stated, the target is an average transition rate of 0.555/million years. We run many repeats (500) of a single population under both conditions (original Model A and environmental disruption Model B), recording the number of years it takes to transition to selfing each time. We then take the reciprocal of the mean length of time, arriving at the average transition frequency. After fixing certain parameters of the models, we search manually for parameters that produce the target transition rate for these conditions. Using the same criterion as Goldberg et al. (2010), we conservatively classify a species as SI as long as it is not completely SC, ie. no polymorphism, approximated as less than 1% of the SI phenotype present in the population; a transition is said to occur when the outcrosser proportion goes below 0.01.

The simulation is a genetic algorithm with a single population, initially fully outcrossing ( $x = 1$ ). We use roulette selection, which is equivalent to a diffusion approximation of selection and drift (Cherry and Wakeley, 2003). The fitness values for outcrossers and selfers are as per eqs. (1a) and (1b).

Upon selection, if the phenotype is selfer, it is added to the next generation, but if outcrosser, it is combined with pollen from another plant in the population. The probability that this mate is an outcrosser, as opposed to selfer, is  $m_x$  (eq. (2c)).

The phenotype that goes into the next generation is from either the selected plant or the mate, with equal probability. This is equivalent to the average effect of crossover for outcrossing plants. The net effect of this selection and probabilistic recombination process is captured in fitness eqs. (2a) and (2b). The trait is also probabilistically mutated according to the (phenotypic, per gene per generation) mutation rate  $\mu$  before being added to the next generation.

After each generation, we check if the population has transitioned to SC ( $x < 0.01$ ) and break out of the current run if this is the case, recording the length of time that has passed. One generation is equal to one year, a working value used by other models of plants in the Solanaceae family (Vekemans and Slatkin, 1994). For a high level overview of the computer simulation's operation, refer to algorithm 1.

## Parameters

Table 1 shows the initial set of parameters for the models. The effective population size  $N_e$  for Solanaceae does vary, but 6000 is within the expected range (Richman et al., 1996). A conservative level of pollen discounting, 0.2, has been chosen initially. As explained, Model A requires that the conditions favour selfing constantly, so a value of  $\delta = 0.3$  has been chosen to fulfil this requirement (see fig. 1(a), 0.3 is below the  $\delta$  equilibrium for  $p = 0.2$ ,  $l = 0$ ). For Model B, the environmental disruption model, we need selective

Table 1: Parameters of the model under Models A and B. Values to be found or manipulated are marked by \*.

## Results

In the first section we present the results from Model A, the model under which species selection directly opposes constant individual incentive for selfing, and Model B, where environmental disruptions bring about temporary individual incentive for selfing. We indicate parameter values under which these alternative low level models exhibit the empirically observed transition rate of 0.555 per lineage per million years ( $0.555\text{E-}6$ ) at the species level. We then go on to present some typical evolutionary trials, exposing the underlying selection mechanics of the models.

### Results from Models A and B

In each case, the resultant transition rate is the mean frequency of transition over 500 trials of the single population genetic algorithm. Parameter values were found by manual experimentation given the fixed values established by the model assumptions, detailed previously in table 1. The output parameter of interest is the phenotypic mutation rate required under each model to bring about the rate of transition observed by Goldberg et al..

|                | $\mu$    | $r$                           | $d$                    | Transition rate |
|----------------|----------|-------------------------------|------------------------|-----------------|

| B <sub>0</sub> | 1.33E-8  | $\langle 1\text{E-}5 \rangle$ | 5000                   | 0.563E-6        |
| B <sub>1</sub> | 2.17E-8  | $\langle 1\text{E-}5 \rangle$ | 3000                   | 0.537E-6        |
| B <sub>2</sub> | 2.17E-7  | $\langle 1\text{E-}5 \rangle$ | 500                    | 0.552E-6        |
| B <sub>1</sub> | 2.17E-8  | 1E-5                          | $\langle 3000 \rangle$ | 0.537E-6        |
| B <sub>3</sub> | 2.28E-8  | 5E-6                          | $\langle 3000 \rangle$ | 0.567E-6        |
| B <sub>4</sub> | 2.33E-8  | 1E-6                          | $\langle 3000 \rangle$ | 0.572E-6        |

Table 2: Parameters and results under Model A (original, no disruption:  $r, d = 0$ ) and B (temporary environmental disruptions:  $r, d > 0$ ). Transition rate should approximate  $0.555\text{E-}6$ . The table is grouped, where values held constant are shown in angle brackets, while others were manipulated to obtain the target transition rate. Result B<sub>1</sub> is repeated in the third group for convenient comparison.

Table 2 shows that a transition rate of approximately  $0.555\text{E-}6$  can be obtained under multiple conditions; either model is able to potentially explain the empirical observations, but with a different necessary value for the mutation rate  $\mu$ . For Model A, the background assumptions are such that there is only one possible value, found to be  $5.17\text{E-}10$ . Under Model B there is more scope for interaction between the parameters during the search. Holding the disruption rate  $r$  at an average of once per 100,000 years ( $1\text{E-}5$ ), rows B<sub>0</sub>, B<sub>1</sub>, and B<sub>2</sub> show that higher mutation rates are required for shorter durations of disruption. Keeping the disruption duration  $d$  at 3000 years, we similarly see from rows B<sub>1</sub>, B<sub>3</sub>, and B<sub>4</sub> that lower values of disruption rate  $r$  require higher mutation rates, but the effect is considerably less significant.

The required mutation rate is more sensitive to the duration of the disruptions than their frequency.

### Example Evolutionary Trials

(a) A final phase of the evolution curve once selfing manages to spread, typical under both models.

(b) An example evolution curve under Model A where SC mutations arise and are lost multiple times under drift before managing to spread and fixate. The final line down on the right continues to full selfing as in fig. 2(a). Note the scale of the y axis:  $x$  does not get below 0.9985 without SC spreading.

(c) An example evolution curve under Model B. The level of pollen limitation, alternating between 0 and 0.2 on the secondary y axis due to disruption, is also shown. Observing the scale of the primary y axis,  $x$  (the top curve) reaches below 0.9965 without SC managing to spread, lower than under Model A in fig. 2(b). The final line down on the right again continues to full selfing as in fig. 2(a).

Figure 2: Example sequences from typical evolutionary runs.

Under Model B, the temporary disruptions in the environment allow SC mutations to arise and begin to spread if they are not lost by drift, and may get further than is typical under Model A. This is illustrated in figs. 2(b) and 2(c), where the different scales of the y axis show that the outcrosser proportion can typically get slightly lower in B without a full SC invasion. This is likely due to the inconsistent selection pressure provided by Model B, as disruptions are brought in and out, shifting the balance of fitness towards and away from outcrossing over time.

Both models produce similar final phases of SC spreading to fixation, as seen in fig. 2(a), as under either model, once selfers reach a certain proportion, selection pressure becomes reinforcing and full invasion becomes highly probable.

## Discussion

Evolutionary models that consider the interaction between multiple levels of the biological hierarchy provide a complex challenge. We have taken Goldberg et al.'s species level empirical data and attempted to realise the individual level processes that give rise to the SI-to-SC species transition rate. Using a genetic algorithm and Lloyd (1992)'s phenotypic model, we discover the mutation rates required under two alternative models, given certain assumptions.

We begin to explore the conditions under which the target transition rate can be produced, and show that there seems to be scope for an environmental model to help explain the evolutionary history of SI and SC in the Solanaceae plant family. Assessing the likelihood of the presented model, or of alternative environmental variation hypotheses, will come down to the plausibility of the required mutation rates. If the mutation rate required of Model A, under the pure species selection hypothesis, is too low, this may suggest individual selection is a significant factor, mediated by environmental conditions. Our Model B presents one such possibility.

The method presented of separating out the individual selection process from the species level process may be applicable to other questions regarding multi-level selection processes. By starting with empirical evidence at the species level and reverse engineering the individual selection pressure using established models, we can explore the real world parameter ranges required to meet alternative theories. These parameters can then hopefully be subject to empirical test, to observe which model obtains.

We did not have time to perform more comprehensive parameter sweeps to provide a robustness analysis. Investigating the relationships between the sets of parameters may prove fruitful as well.

In future work, alternative theories of environmental variation should be explored. In the first instance, an alternative take on Model B would be to have pollen limitation  $l$  vary continuously in the background, rather than being manipulated by binary disruption events. It may be that gradual or

shallower yet longer dips in dispersal can produce similar rates of transition, for example. More complex models of inbreeding depression and pollen discounting should also be incorporated, as unforeseen interactions between environmental variation and fitness over time may be exhibited.

In summary, we have examined within-species dynamics, under individual selection, that can account for the species level rate of transition that has been empirically observed. Given certain conditions, we obtained the values necessary for the mutation rate to explain the data under two alternative models. Individual based modelling techniques were effectively employed, enabling the analysis of these stochastic models under environmental interaction. By attempting to establish the details of the biological interactions below the species level, we indicate parameter values that may support or reject the original species selection hypothesis.

# Family Bird: A Heterogeneous Simulated Flock

Jure Demšar<sup>1</sup> and Iztok Lebar Bajec<sup>1</sup>

<sup>1</sup>Faculty of Computer and Information Science, Tržaška cesta 25, 1000 Ljubljana, Slovenia

## Abstract

Since the phenomena of bird flocking is so fascinating, there is no shortage of computer models that try to visualize this mesmerizing spectacle. However, the quality of artificially modelled flocks is currently not on par with their counterparts in nature. We believe the main reason for this lies in the homogeneous structure of flocks in computer models. In this article we show how just a pinch of heterogeneity can increase the repertoire of displayed behaviours.

## Introduction

At first glance the mesmerizing phenomena of bird flocks and fish schools appear very complex, but according to existing literature the underlying principles may be quite simple. In 1980s two groups of researchers working independently showed that a flocking-like behaviour can be produced in computer simulations if artificial animals (*animats*) follow a few simple rules (Reynolds, 1987; Heppner and Grenander, 1990). Reynolds introduced three drives – *cohesion*, *separation* and *alignment*. Cohesion drives the observed animat to stay close to its neighbours; separation forces it to avoid collisions by steering away from animats that are perceived as too close; alignment imitates the desire to synchronize speed and heading with nearby animats.

The main problem of models that use these three (or similar) rules is that the appearance of the displayed behaviour is far from the mind-blowing spectacle one might admire in nature. The behaviour of computer produced flocks was very rigid and stereotyped. Many models thus introduced mechanisms that induce some randomness to the motion of the animats (Heppner and Grenander, 1990; Vicsek et al., 1995; Couzin et al., 2002; Hildenbrandt et al., 2010). The authors defend this approach by saying these mechanisms simulate wind gusts, obstacles and other random factors. We disagree with their reasoning since obstacles do not just appear at random, and wind gusts are not random per individual. Even with the addition of randomness the result was nowhere near as breathtaking as flocking in nature; the flocks in computer models seldom split into smaller flocks that rejoin after manoeuvring on their own for a while. We believe the main

deficiency of artificial flocks is their assumption that all the birds in the flocks have the same characteristics. The birds in natural flocks often differ in size, gender, age, and even species (Lebar Bajec and Heppner, 2009; Jolles et al., 2013). As shown in (Jolles et al., 2013) the flock's structure and social relationships between individuals greatly impact the behaviour of the flock. To bring computer models closer to flocks in nature, we developed a heterogeneous model that includes social relations.

## Methods

Our model uses fuzzy logic to describe the individual bird's drives (Lebar Bajec et al., 2005). These drives depend on a specific number of nearby neighbours, regardless of their distance (Cavagna and Giardina, 2008). Inter-bird occlusion is taken into account, i.e. nearby neighbours occlude those farther away (Kunz and Hemelrijk, 2012). In contrast to other models we have included social relations. We have included two types of animats solitary and social. The separation and alignment are the same for both types, but the cohesion drive is different. For social animats it models the desire to stay close to members of the same social group (e.g. family), for solitary animats it models the desire to stay close to nearby neighbours regardless of their affiliation.

To test the behaviour of the upgraded model we ran several simulations. The length of every simulation was 1800 frames (30 frames equals one second). The flock consisted of 20 animats. During the first simulation all 20 animats were solitary, so the flock was completely homogeneous. In our second simulation we had 15 solitary animats and 5 animats that belonged to the same social group. In our third simulation the flock consisted of 2 social groups with 5 animats in each and 10 solitary animats. Our last configuration had 3 social groups consisting of 5 animats each and 5 solitary animats. The flocks were left to roam freely inside a circular roosting area of 140 body lengths in diameter.

During our simulations we measured the *order* of the group (Vicsek and Zafeiris, 2012) and the number of flocks. We defined a *flock* as a group of animats that have influence on each other's behaviour. So to have two flocks there need

to be two groups of animats, in which no one from one group influences the behaviour of an animat in the other group, and vice versa. The order of the group is measured via the normalized velocity  $\varphi$ , which is calculated as

$$\varphi = \frac{1}{Nv_0} \left| \sum_{i=1}^N \vec{v}_i \right|. \quad (1)$$

## Results

As it can be seen from Figure 1, the behaviour of modelled animats is much more dynamic if the number of social groups is higher and the number of solitary animats is lower (more heterogeneity). The order of a homogeneous flock declines only when it reaches the edge of the roosting area and performs a U-turn. The behaviour is more diverse as well; splits and joins of flocks that consist of more than one social group are quite common and do not appear only at the boundaries of the roosting area.

Figure 1: How the value of  $\varphi$  changes through time in differently structured flocks.

But the increase of the number of social groups and the decrease of solitary animats have a downside. A very low number of solitary animats produces separate flocks that fly independently and only seldom rejoin in a larger flock. Figure 2 shows the importance of solitary animats, as they are the main reason of re-joins of split flocks. So the most “natural” results were achieved when the number of solitary animats was the same as the number of social animats. Videos of simulations are available at <http://lrss.fri.uni-lj.si/cb/families.html>.

## Conclusion

Our simulations suggest that homogeneity might be an important factor for the lack of diversity in the displayed behaviour in computer models. Just with the addition of simple social relationships we managed to achieve complex manoeuvres in the form of splits and joins that resemble natural movements. What could be achieved with more complex heterogeneity is still to be researched.

# Population Dynamics of Centipede Game using an Energy Based Evolutionary Algorithm

Pedro Mariano and Luís Correia

LabMAG – Dep. de Informática, Faculdade de Ciências, Universidade de Lisboa, Portugal  
plmariano@fc.ul.pt

## Abstract

In the context of Evolutionary Game Theory, we have developed an evolutionary algorithm without an explicit fitness function or selection function. Instead players obtain energy by playing games. Clonal reproduction subject to mutation occurs when a player's energy exceeds some threshold. To avoid exponential growth of the population there is a death event that depends on population size. By tweaking with the relation between payoff and energy and with death event, we create another dilemma that a population must overcome: extinction. We demonstrate this phenomena in the Centipede game. Simulations show that if players can only play one of the two positions of this asymmetric game extinctions are common. If players are versatile and can play both positions there are no extinctions.

## Introduction

Game Theory provides a series of tools to model how agents interact (Gintis, 2000; Shoham and Leyton-Brown, 2009; Fudenberg and Tirole, 1991). Evolutionary Game Theory (EGT) studies the population dynamics of individual agents (Maynard Smith, 1982; Hofbauer and Sigmund, 1998). Therefore it is natural to use games as a starting point in any study on interaction dynamics be it at the individual level or at the population level. Nash Equilibrium is one of the most important concepts in Game Theory (Nash, 1951). Its equivalent in population dynamics is Evolutionary Stable States. It posits that no player has incentive to move from its strategy because he would be worse. Since the publication of this result, several games have been proposed that have cooperative dilemmas: if players follow the equilibria they are worse off. Among these games we cite Prisoner's Dilemma (PD), Centipede, Ultimatum and Public Good Provision (PGP). When these games are repeated a known number of times, the theory, through backward induction (Fudenberg and Tirole, 1991; Shoham and Leyton-Brown, 2009), predicts the demise of cooperation. When players have limited resources such as memory, they may lack the ability to count how many stages have passed, so they cannot perform backward induction. In fact, earlier work on using finite state automata to play games has

shown the prevalence of cooperation (Neyman, 1985; Axelrod, 1997).

The capability of players finding the equilibria as recently been shown to be a hard problem. Research on the complexity of computing Nash Equilibria has established it as belonging to class PPAD or *polynomial parity argument, directed version* Papadimitriou (1994). This class sits between complexity classes FP and FNP which generalise classes P and NP from decision problems to functions computable in polynomial time. Examples of classes of games in this class include general sum games in normal form with two or more players belong to this class (Chen and Deng, 2006; Daskalakis et al., 2009), repeated games (Borgs et al., 2010) or stochastic games. These results show that if player wants to compute the equilibria he would spend an exponential time. Clearly biological system do not sit still that long. In fact their computational resources are limited and thus they have to use them in some efficient way. Early research on artificial systems used finite-state machines to model the behaviour of agents (Axelrod and Hamilton, 1981). This approach when applied to cooperative dilemma games resulted in agents playing the strategy profile that result in higher social payoff.

Instead of focusing on the (in)capability of computing the Nash Equilibria, one may turn into to the population dynamics. If the population is some evolutionary stable state this is not the result of players computing the best response to their peer in order to become dominant in the following generations. Instead it is a combination of population-level mechanisms such as mutation, selection and stochastic events.

Evidence from experimental play (Camerer, 2003) showed that people do not follow the equilibria and that instead cooperation is prevalent in many places. Therefore it may be counterproductive to discuss the equilibria of some system or the rationality of players (Aaronson, 2013). Instead, one should focus on the mechanisms behind the behaviour of real players and population and how they have overcome a series of dilemmas. Partner selection (Aktipis, 2004) or player connectivity (Santos and Pacheco, 2005) explain the prevalence of cooperation in these type of games.

We should be focusing on how evolution has overcome a series of dilemmas to produce the biodiversity that we can appreciate. One special dilemma is extinction. If evolution cannot surpass it then the model or system is not viable. Therefore it is important to consider a model that explicitly takes into account and allows it and does not have mechanisms to circumvent it by magic repopulation or by keeping a constant flow of energy resources (Yaeger, 2009).

In this paper we address the extinction dilemma. This event can appear in cooperative dilemmas because players choose the lower payoff profile. In order to introduce this event we have to create an Evolutionary Algorithm (EA) with varying population size. This has already been done in artificial ecosystems (Lenski et al., 2003; Ray, 1997) although the focus was not the study of how to avoid extinctions. The model that we propose is generic in that it can be applied to any game, just as the replicator equation (Taylor and Jonker, 1978), the Moran process or an Individual Based Model (IBM) (Grimm et al., 2006; McLane et al., 2011) can be applied to any game. This is done by simply interpreting a game as an energy transfer process and creating a player's life cycle that is driven by the energy acquired by playing games.

The rest of this paper is organised as follows. In the next section, we start by reviewing related work on models that can be used to study population dynamics while focusing on the ability to study extinctions. The following section is the major contribution of this paper as we describe the EA we have developed. The next section presents our characterisation of the Centipede game. Afterwards we present simulation results of our algorithm with the Centipede game. We finished the paper with a discussion section and a conclusions and future work section.

## Related Work

The study of evolutionary traits has used models based on differential equations such as the replicator equation (Taylor and Jonker, 1978; Nowak, 2006; Hofbauer and Sigmund, 1998; Maynard Smith, 1982; Gintis, 2000; Hofbauer and Sigmund, 2003) or the Moran process. They have been used to describe the broad behaviour of systems (Meadows et al., 1972).

There are a set of assumptions behind replicator equation (Roca et al., 2009). One assumes a considerably large or infinite population. Another assumes a well mixed-population such that everybody plays with everybody else. A similar approach is randomly pairing players. These are unrealistic assumptions and have led to alternative proposals. Among them are structured populations where players are placed in the nodes of some graph and interactions are restricted to links between nodes (Nowak et al., 1994; Szabó and Hauert, 2002). Despite not allowing varying population size, they have been used to model scenarios that may cause extinctions such as climate change (Santos et al., 2012).

Agent or IBM address the difficulties of creating a formal model of a complex system (Forrest and Jones, 1994). After a series of artificial ecosystems populated with these type of individuals (Ray, 1992; Lenski et al., 2003; Yaeger, 1994) specific protocols to construct such systems have emerged (Grimm et al., 2006).

There are IBMs that analyse the possibility of extinctions but they do that in specific contexts such as model population growth of endangered species (Beissinger and Westphal, 1998), tree mortality (Manusch et al., 2012), impact of logging activities in bird species (Thin et al., 2012). Some of these models are characterised by using specific differential equations or operate at higher level than the individual. Often they are specific to their case study and their methods are not directly transferable to another scenario.

McLane et al. (2011) provides a review of IBM used in the literature of ecology to address the issues of managing ecosystems. They presented a set of behaviours that individuals can choose in their life cycle: habitat selection, foraging, reproduction, and dispersal. In the papers that they reviewed, some used all the behaviours in the set while others used just one. Such set of behaviours could constitute the set of actions of some generic game played by animals. Moreover we can divide them in two sets, one where an animal obtains energy (foraging) and a second where an animal spends energy (habitat selection, reproduction, and dispersal).

While standard EGT models use either infinite populations or constant finite populations, IBMs have been used to model scenarios where populations could go extinct. This can happen because a player's actions do not provide him enough resources to reproduce. While their models are often used in specific problems it is important to create a general evolutionary algorithm that can be applied to any game and where extinctions can occur independently of game characteristics.

## Evolutionary Algorithm Description

The Energy Based Evolutionary Algorithm (EBEA) we have developed is characterised by a game. The concept of a game as an energy transfer is a redefinition of the payoff function. A game  $G$  is a tuple  $(N, A, E)$  where  $N$  is a set of  $n$  players,  $A = \{A_1, \dots, A_n\}$ , where  $A_i$  a set of actions for player  $i$ , and  $E = \{e_1, \dots, e_n\}$  is a set of payoff functions,  $e_i : A_1 \times \dots \times A_n \rightarrow \mathbb{R}$ , which we interpret as an energy flow. In this context, players are characterised by a strategy  $s$  and an energy level  $e$ . Each iteration of the algorithm has three phases:

**play** in this phase all players play the game and update their energy. Partners are selected randomly.

**reproduction** in this phase the players whose energy is above threshold  $e_R$  produce one offspring and their energy is decremented by this value. The offspring is mu-

tated with some probability. This is asexual reproduction with mutation.

**death** in this phase, the entire population goes through a carrying capacity event where the probability to die depends on population size. This contrasts with our previous work (Mariano and Correia, 2011) where the event mixed population size with player's age.

Regarding the relation between the payoff function and the energy function, we have extended our work in Mariano and Correia (2011). In order to compare the evolutionary dynamics of games with different payoff functions we scale the payoff  $\pi$  obtained by a player. This gives the following equation:

$$e \leftarrow e + \frac{\pi}{\bar{\pi} - \underline{\pi}}, \quad (1)$$

where  $\bar{\pi}$  and  $\underline{\pi}$  are the highest and lowest payoff obtainable in game  $G$  respectively, and  $e$  is a player's energy. The rationale for this equation is that player's energy increases proportionally to the payoff obtained in the game.

The chromosome codes the strategy to play the game  $G$ . The coding may range from direct, where actions are explicitly defined for all possible histories, to compact, where the strategy is represented in a symbolic form, for example by a set of rules to be executed by the phenotype. In both cases the result is either a specific action, for a pure strategy, or a probability distribution over the set of actions, for a mixed strategy. Notice that mutation operator must be adapted to the coding used.

Regarding the phenotype of a player, besides executing the strategy coded in the chromosome, it has associated an energy level. This is used for reproduction. As we have seen, an individual reproduces when his energy is above threshold  $e_R$ . This may also be considered as an indirect fitness assessment.

Unlike our previous work, in this paper we use random partner selection. Although this is an unrealistic assumption, we want to present a core evolutionary algorithm. From this core algorithm we can study what mechanisms are necessary to escape extinctions. In the context of PGP we have shown that partner selection can escape extinctions and promote cooperation for some parameter settings (Mariano and Correia, 2011).

The goal of this paper is to show what population dynamics we can observe with our evolutionary algorithm using Centipede as the game. In our current implementation of the algorithm, the random partner selection does not take into consideration if the game is symmetric or not. This means that in asymmetric games incorrect players may be matched. For instance, in the Ultimatum game two dictators may be paired. In this case both get zero energy.

In order to avoid exponential growth, in each iteration of the algorithm all players go through a death event. While in previous work we had a single event that mixed population

size with player's age, in this paper we only use population size. Death by old age is optional and is not strictly needed to avoid exponential growth. The probability of a player dying because of population size is:

$$P(\text{death population size}) = \frac{1}{1 + e^{6 \frac{K - |\mathcal{P}|}{K}}}, \quad (2)$$

where  $|\mathcal{P}|$  is the current population size and  $K$  is a parameter that we call carrying capacity. This probability is a sigmoid function. The exponent was chosen because the logistic curve outside the interval  $[-6, 6]$  is approximately either zero or one. In the advent of the entire population duplicating size, it will not go from a zero probability of dying to certain extinction.

From the description of our algorithm it is clear that there is no explicit fitness function nor selection function. Instead, the energy update function represented by equation (1) combined with the reproduction threshold induce a process where players that acquire more energy per game are able to reproduce faster (and spread their genes) than a player that gains less energy. A fit player is one whose strategy allows him to obtain more energy in the current population state.

The dynamics of this algorithm can be characterised by a Markov Chain. Supposing a well-mixed population, each state encodes a bag of pairs  $(s, e)$ , where a pair represents a player with strategy  $s$  and energy level  $e$ . Due to the carrying capacity we can impose a limit on the number of states, such that the probability of the population size passing this limit is negligible. This limit can be computed from equation (2). The Markov Chain has at least one absorbing state, namely the empty bag which corresponds to an extinction.

If there is a strategy profile of the underlying game that gives the minimum payoff to all players, then by equation (1) players using the corresponding strategies cannot increase their energy. This means that paths from states containing only strategies from this type of profile can only go to the empty bag state. However the time to walk this path may be large because death probability becomes negligible. From a practical standpoint the corresponding Markov states can be characterised as almost absorbing.

If there are no such strategy profile, then from any state other than the empty bag state there is a positive probability to reach any state in the Markov chain. This probability depends on event *death population size*, on event *mutation*, and on the *mutation operator*.

## Centipede Game

The Centipede game is a sequential game of perfect recall where in each stage a player decides if he keeps a higher share of a pot of money or decides to pass the pot to the other player (Rosenthal, 1981; McKelvey and Palfrey, 1992; Rand and Nowak, 2012). If the player keeps the higher share the

game stops. If he passes the pot is increased by some external entity. The game has some fixed number of stages. The payoff structure is constructed such that the payoff the deciding player obtains at stage  $t$  is higher than he obtains at stage  $t + 1$ . The game can be characterised by the initial size of the pot,  $p_0$ , how the pot is increased,  $p_i$ , and the pot share given to the player that decides to stop or not,  $p_s$ . We consider two methods to increase the pot: an arithmetic progression with difference  $d$ , represented by  $p_i = a(d)$ ; and a geometric progression with ratio  $r$ , represented by  $p_i = g(r)$ . The pot size at stage  $t$  is given by:

$$p(t) = \begin{cases} p_0 + d(t-1) & \text{if } p_i = a(d) \\ p_0 r^{t-1} & \text{if } p_i = g(r) \end{cases} \quad (3)$$

From this equation, the payoffs at stage  $t$  are  $\pi_D(t) = p(t)p_s$  for the player that stops and  $\pi_{-D}(t) = p(t)(1 - p_s)$  for the other player. The subscript  $D$  represents the player that decides to stop.

Figure 1a shows an example of the Centipede game for some parameter settings. Time goes from left to right. Since Centipede is an asymmetric game, we will consider two types of players: *first* represents the players that decide in odd stages; *second* represents the players that decide in even stages. In the extensive form game shown in figure 1a the types are represented by numbers one and two, respectively. In the last stage if player two decides to stop he receives the higher share of the pot. Otherwise the pot is increased but he receives the lower share.

In this paper we use a variant where the pot size is increased and then split as given by  $p_s$ . The parameters must obey the following set of conditions:

$$\begin{cases} p_s > 0.5 \\ d > 0 \wedge (p_0 + d)(1 - p_s) < p_0 p_s & \text{if } p_i = a(d) \\ r > 1 \wedge p_s > r(1 - p_s) & \text{if } p_i = g(r) \end{cases} \quad (4)$$

The second part in the second and third conditions represents the fact that  $\pi_D(t) > \pi_{-D}(t + 1)$

To decrease the number of parameters, we set the initial size of the pot to one,  $p_0 = 1$ . The admissible parameters of Centipede given by equation (4) can be represented graphically as shown in figure 1b.

The two methods to increment the pot create different pressures on players during our evolutionary algorithm. The difference in energy obtained per game is higher in the geometric method than the arithmetic variant. This means birth rate are different for both methods thus population viability is higher in the arithmetic variant.

The chromosome contains two genes. The first gene (binary) represents the player type while the second gene (natural number) represents the stage where it decides to stop the game. We will use  $t_\varepsilon$  to represent an action of the player that moves first and decides to stop the game at stage  $t_\varepsilon$ . Likewise, we will use  $t_s$  for the other player. Recall that in our

|       |                         |                                |

current implementation of the algorithm, if players of the same type are paired, they obtain zero energy. Otherwise, they play the game.

## Experimental Analysis

### Simulation Settings

The purpose of the experiments is to study what kind of dynamical behaviour we can achieve with this new EA. Since the population size may vary, extinctions may happen because players cannot get enough energy to reproduce and they are slowly killed. We have tested different combinations of parameters. Regarding the parameters of the EA we varied only the carrying capacity in order to assess its impact on the occurrence of extinctions. We opted for using a single value for the mutation probability and reproduction threshold parameters. The number of iterations of the algorithm was  $10^5$ . Regarding the game parameters, we varied the number of stages in order to assess the amount of strategies on the population dynamics. We used high pot share to strengthen the backward induction argument. As for the pot increase method we opted to increase the pot share as given by equations (3) and used different differences or ratios. Table 1 shows the parameter values used in the experiments.

The initial population consisted in 10 players with chromosome type *first* and 10 players with chromosome type *second* both with the highest time to stop the game,  $t_\varepsilon$  and  $t_s$ . Whenever a player exceed the reproduction threshold and produce an offspring, he was subject to mutation with probability 10%. The mutation operator consisted in adding or subtracting to the time to stop the game,  $t_\varepsilon$  or  $t_s$ , a discrete Gaussian distribution with average zero and standard deviation one. The resulting value was constrained in the interval one to the number of stages in the game.

For each parameter combination we performed 10 runs in order to get some statistical information on the population dynamics. For each simulation run, per iteration, we recorded population size, number of births, number of deaths, number of players with each type and average time to stop for each type. If the population size dropped below two we stopped the simulation.

Figure 2 shows the plot of the probability of the event *death population size*, as given by equation (2) for the tested

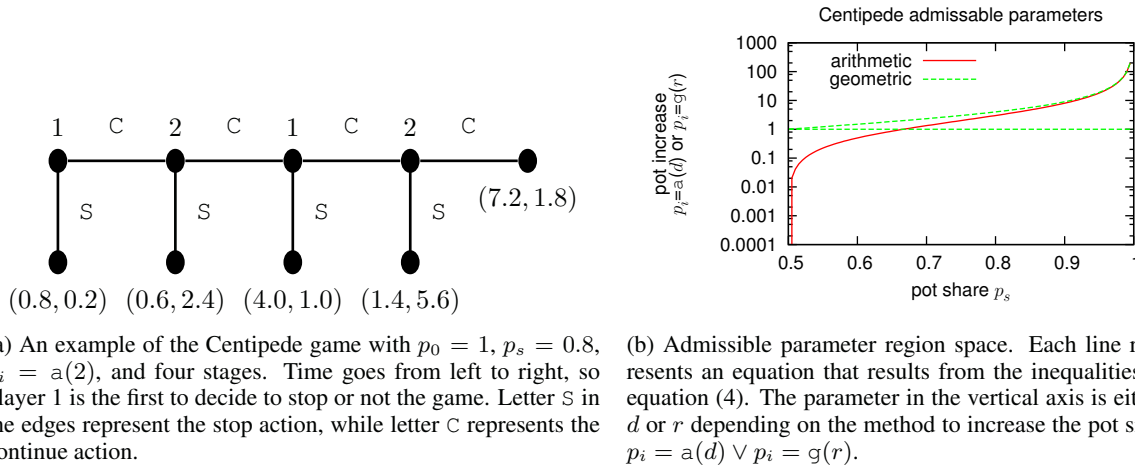

Figure 1: Schematics of the Centipede game used in the experiments.

 Figure 2: Plot of the probability of event *death population size* as given by equation (2) for different carrying capacity values.

carrying capacity values. As the parameter increases the plot becomes smoother meaning population size is unlikely to remain nearer the value of  $K$ . Moreover, as  $K$  increases, it becomes increasingly unlikely that the population doubles at specific iterations as more players had to synchronise their reproduction behaviours.

## Simulation Results

The major contribution of EBEA is the possibility of extinctions. In the evolutionary model that we have used extinctions can only occur if the population size drops below the number of players of the game. In the work that we report in this paper it is two. Another possibility is one of the player types extinguishing from the population. Regarding simulations using geometric pot increase, Figure 3 shows the number of simulations where some type of extinction occurred as a function of carrying capacity (vertical axis) and number of stages (horizontal axis). There is not a clear trend although a higher number of extinctions of second players compared to

first player extinctions is clear and extinctions of first players tend to increase with number of stages. Simulations with the arithmetic pot increase resulted in less extinctions for both types of players with around 45% less for second players and 95% less for first players. This is mainly due to a smaller difference (compared to the geometric increase) between stage payoffs.

We can also analyse what strategies are more common under this evolutionary algorithm. In the simulations that we performed the average time to stop the game,  $t_f$  and  $t_s$ , showed a decreasing trend to the smallest value, meaning players become less cooperative. Rand and Nowak (2012) argue that population size and selection strength affect the prevalence of cooperator strategies, meaning players that stop the game latter. In their paper they have used the geometric pot increase variant. However, their strategies could play both types. Given randomisation over partners, this means that on average a player is better never stopping the game. If we take the example of the Centipede game in figure 1a their players would get on average a payoff of  $(7.2 + 1.8)/2 = 4.5$ . When they decrease selection strength the weight of a player's payoff in his fitness decreases and selection becomes a random process. They only observe higher levels of cooperation when selection strength is mild, but we suspect that the cause is the ability of players playing both types. We have performed some simulations with our evolutionary algorithm where players could play both types. In these simulations we never observed an extinction. Regarding the geometric pot increase, we went from a scenario where some type of extinction occurred in 78% simulations to a scenario with no extinctions. Moreover players stopped the game at later stages. Switching from specialist players that only played one type to generalist players that played both types solved the problem of extinction.

This fact is very important given that, although our algorithm does not have an explicit fitness function, it has a high selection strength. If we examine the population dynamics of single simulations we often observe variations in population size that are correlated with player type's abundance and their strategies. When they stop the game at latter stages, they are able to acquire energy faster thus produce more offsprings per iteration. Therefore given two populations one that stops earlier and another that stops later and we run our algorithm without mutations, the second population outgrows the first.

## Discussion and Comments

The EA algorithm that we have presented does not have an explicit fitness function nor selection function. Instead players must acquire energy in order to be successful. This is an approach similar to individual-based models such as Echo (Forrest and Jones, 1994) or Avida (Lenski et al., 2003). Their models are ecosystems that use very specific games. Indeed one could formalise the interactions performed by the individuals in those systems as a game. With our approach we interpret games as an energy transfer process. In these systems there is also an energy concept. Individuals must perform some tasks in order to obtain energy tokens that are used to generate offsprings. While offsprings usually replace some stochastic chosen individual, in our approach they are added to the population. This is a similar approach to Yaeger (2009).

Scaling allows us to compare the evolutionary dynamics of games with different payoff functions: consider the number of offsprings per iteration. We could remove scaling, which means that energy range is equal to payoff range.

The EA has at least one absorbing state, namely the one corresponding to an empty population. A state of the corresponding Markov Chain may not be reachable if the population is filled with players that only get the lowest payoff. Therefore the only path is towards extinction, which can take a long time as we have seen in simulations using Centipede. This could be resolved if we had a death by old age event. This would put extra pressure on a population to escape extinction.

This process (energy dynamics and population control) is different from other approaches (Aktipis, 2004; Ray, 1997; Lenski et al., 2003). Even when they use energy, the focus is not the evolutionary algorithm and extinctions are not possible. Interactions between players are mediated by some game, which determines how much energy a player obtains. Therefore it is applicable to any game, either some simple game such as Iterated Prisoner's Dilemma (Aktipis, 2004) or a complex game where strategies are computer programs (Lenski et al., 2003). Population control is also independent of the game as only depends on population size.

Figure 3: Results from the simulations with geometric pot increase. The plots show the number of simulations where first or second players got extinct – the higher the number of simulations the bigger is the square.

## Conclusions and Future Work

We presented an Evolutionary Algorithm (EA) that fits in the field of Evolutionary Game Theory (EGT) and of Individual Based Model (IBM). That is to say, players go through the stages of birth, growth, reproduction and death all mediated by some game that is characterised as an energy transfer process. A game instead of having a set of payoff functions, has a set of energy transfer functions. A player's chromosome codes his strategy and a player's phenotype executes the coded strategy and has associated an energy level. Reproduction occurs when a player reaches some energy threshold. In order to avoid exponential population growth, a death event, by population size, is performed in every iteration of the algorithm. This creates a new dilemma that players of a game must face, namely extinction.

Our EA can be compared to other models where energy managing is the focus (Lenski et al., 2003; Yaeger, 2009; Ray, 1997). While in these models extinction is circumvented or is not the focus, in our algorithm it is a dilemma and a danger that a population must keep evading. This is a harder dilemma than cooperation, because while with the latter a population may stay in some non-cooperative state for a long a time, an extinction is a dead end, it is the only absorbing state of our algorithm.

The algorithm is generic has it can be applied to any game, be it a simple one such as Centipede, Prisoner's Dilemma (PD), Ultimatum or PGP or a complex game whose action space is not explicitly given but instead there is some logical description to construct strategies to play the game.

We have applied our EA to the Centipede game. This is an asymmetric game with two types of players. Extinctions occur when players can only play one of the two types. This dilemma can be circumvented if players are able to play both types. Contrasting with Rand and Nowak (2012) we did not have to lower selection strength.

Concerning future work, we have some preliminary results regarding the application of our algorithm to other games such as Ultimatum, PGP or 2-player 2-action games. In the results obtained so far we have seen the occurrence of extinctions. We plan to increase the extinction pressure on players by adding a death by old age. This puts pressure on players to find mechanisms to avoid the fate of extinction. A possible mechanism is partner selection (Mariano and Correia, 2011). Another avenue of research is considering variable player's energy as is done in artificial ecosystems (Yaeger, 2009; Ray, 1997). This means that the fitness function can be interpreted as an energy transfer process not only from the environment to the player but backwards. This puts extra pressure in games that have costs associated to some actions such as PGP or some variants of 2-player 2-action games.

## Cooperation of two different swarms controlled by BEECLUST algorithm

Tobias Meister, Ronald Thenius, Daniela Kengyel and Thomas Schmickl

Artificial Life Laboratory, University of Graz, Austria.  
ronald.thenius@uni-graz.at

### Abstract

In this work we investigate how two autonomous agent swarms, controlled by the BEECLUST algorithm are able to cooperate. The task is to locate two different target areas, which are located near each other. Therefore we developed an individual-based NetLogo model to simulate two different agent swarms moving in a temperature gradient. Both agent swarms are controlled by the BEECLUST algorithm, which is inspired by honeybee behavior. We found out that the two cooperating agent swarms are able to locate the target areas, independent of the ratio of the agents.

### Introduction

An eusocial insect colony, which consist of large numbers of individuals can be interpreted as a “superorganism” (Oster and Wilson, 1979). This superorganism is able to solve more complex tasks than the single individual members of the superorganism. The thermal reaction of worker honeybees (Ohtani, 1992), which leads to thermal homeostasis in the honeybee colony, is an example for the self-organisation and the swarm-intelligent behavior (Millonas, 1992) of social insects and one main inspiration for the experiments described in this paper. Several studies (Heran, 1952; Ohtani, 1992) have shown that young honeybees prefer to aggregate in, or near an area with a surrounding temperature of 36°C. The bees move randomly and form longer lasting clusters in warmer, than in cooler zones. We use this simple, but efficient behaviour of honeybees for our experiments. The algorithm derived from this behaviour is called BEECLUST (Bodi et al., 2012, 2011; Schmickl and Hamann, 2011). It is based on the following simple rules:

- (1) The agents move randomly through the arena. Whenever an agent detects an obstacle, it stops and checks whether the obstacle is another agent or a wall.
- (2) If the obstacle is a wall, the agent turns randomly and continues with step 1.
- (3) If the obstacle is another agent, the agent measures the local temperature and calculates his individual waiting time, dependent on the local temperature, according to a

sigmoidal function.

- (4) After the waiting time is over, the agent continues with step 1.

These simple actions of individual agents lead to resource-saving behaviour. Recent works (Kengyel et al., 2011; Kernbach et al., 2009) have shown that artificial agents controlled by this algorithm react flexible regarding environmental changes. In the work at hand we investigate how honey bees age polyethism influences this system. Age polyethism means that in a honeybee colony individuals of the same age perform the same task, and that a given task is often associated with a given age. Examples for such tasks are, collecting nectar in the environment, brood care and the cleaning of the honeycombs. The location of these tasks are not always spatially separated, but can be located near each other, or even within the same area, e.g., broodcare and wax manipulation. It was shown by Bodi et al. (2012) that agents, controlled by BEECLUST, that have identical sensors, but differ regarding their temperature optimum, are able to cooperate well in a complex environment. The question we raise here is, how good can two different groups of agents, that have different sensors (and therefore different tasks) cooperate, if the tasks are located near each other. Based on the results of Bodi et al. (2012), who described the negative influence of jamming effects on groups of agents operating in the same area, and the positive affects of cooperation subgroups we formulated the following hypothesis: Two non-identical agent swarms controlled by BEECLUST are able to cooperate for a given ratio of the agents in the two groups.

### Materials and Methods

To answer this question we performed and simulated our experiments in NetLogo (Wilensky, 1999). The simulated area has a size of 16x16 patches. We implemented two different task-areas with a distance of 5 patches and two different agent-swarms *A* and *B*, acting parallel in the same environment. Both swarms had the same properties and comply with the rules of the BEECLUST algorithm. The two differ-

Figure 1: Absolute number of  $A$  agents, aggregated in  $T_A$ ;  $n = 100$ .

ent task-areas  $T_A$  and  $T_B$  were implemented as gradients in the environment, scaling from a value of 1 in the maximum to 0 in the environment. The size of  $T_A$  was the quarter of the size of  $T_B$  to simulate a highly specialised task near an area of a more general task.

As mentioned above the length of the waiting time of a single agent is determined by the local value of the gradient. The sigmoidal waiting-curve was identical for both agent-swarms  $A$  and  $B$ . The maximum waiting time for both swarms was 1000 timesteps.

We observed and analysed the percentage of agents of  $A$  aggregated at  $T_A$ . The tested population size, including  $A$  and  $B$ , ranged from 3 to 20 individuals. The ratio of  $A$  to  $B$  was varied from 0.2 to 1, rounding was always done towards the next bigger number of  $A$ . Each experiment ran for 3600 timesteps and was repeated 100 times.

## Results and Discussion

It showed, that, by increasing the total amount of agents, the average number of  $A$  increased linearly in the target area  $T_A$  (see figure 1). Surprisingly it further showed, that, in contrast to our hypothesis (mentioned above), the relative amount of  $A$  in the target zone was highly stable against changes of the ratio of  $A$  to  $B$  (see figure 2). This means, that even a single agent can operate within a group of agents with another task (or even another sensory system) without any loss of efficiency. Due to this we can falsify our hypothesis, that the cooperation of two BEECLUST controlled groups of agents is depending on the ratio of these two groups. To which degree these results can be used in the field of swarm robotics to develop selforganised heterogeneous robot swarms based on BEECLUST is the topic of ongoing research at the moment.

### Abstract

This paper presents a system that investigates the sonification of wave interaction in a performance space and its interaction with a live performer – the illumination of sonic activity within a real space, in contrast to conventional ALife algorithmic, event- or material-based approaches. The model maintains three parallel representations of the entire live/virtual system: wavespace, symbol space and performance space. The cross-modal analysis and representation of behavior is important to the evolution of the system, which displays emergence on multiple levels of structure. Micro-evolution takes place within the population of wave-emitting and –listening agents. A higher level of structure emerges from their aggregate in interaction with the live performer, and a formal level as symbol space learns from the performer. Cross-modal representation is seen as a significant factor in the evolution of Western art music, in the development of multi-leveled structure and of work that affords many dimensions of engagement. We discuss the nature of knowledge produced through working with such systems and the role of the subject in ALife-generated knowledge. New models of simulation-derived knowledge are seen as important to cultural understanding.

### Introduction

#### ALife and creative music systems

The relevance of the ALife paradigm to music is well established. Dynamic, evolving populations of behaviors interacting within a constrained space, the emergence of structure unforeseeable from initial conditions, the role of self-simulation and learning and the negotiation of otherwise intractable networks of relationships are system properties that resonate with musical minds.

ALife approaches are particularly attractive to artists working in real-time or interactive environments (see, for example, Miranda 2011, Miranda and Biles 2007). Stricter algorithmic systems are locked within their fixed aesthetic and behavioral dimensionality. ALife architectures appear to be a way of distributing creativity (you can't make 44,100 good decisions a second); composer, performer or environment effectively become co-agents or super-agents. At the same time, there is often a suggestion that such systems in turn might reveal something of the mysteries of music, or of human aesthetic responses, or of sound-based evolution. In the general case, we are dealing with a constructive metaphor; any

verisimilitude is aesthetic. This is not to discount the knowledge inherent in such experience. Indeed, we shall discuss below how the example of an ALife music system can usefully raise questions about the relationship of the subject with such models and the nature of knowledge thus produced.

Interactive music applications have been the most fertile area for development. Technology affords exploration of the space between conventional notions of improvisation and composition, a space non-navigable by traditional means. Concepts such as real-time composition present non-trivial questions as to the relationship between apparently opposed activities of instantaneous decision-making and reflective architectural planning – apparently, because the instant (James's *specious present*) is crucially informed by intention, expectation and habit, and formal architecture is invariably modulated by the sequential, situated development of initial conditions.

#### The present system

ALife-based music systems tend to work on an event basis. That is, they deal with notes of sound objects or MIDI data. Such decisions are pragmatic (this devolves much of the processing), perceptual (we tend to think we listen to music in terms of notes) and cultural (the study of Western music remains largely text- or symbol-based). Artists such as Ryoji Ikeda and Carsten Nicolai work with the evolution and interference of wave-forms, but as entities abstracted from their environment (Ikeda and Nicolai, 2011). Feedback-based work exploits sonic characteristics of particular spaces and technologies (Alvin Lucier's *I am sitting in a room* and Nicolas Collins' *Pea Soup* are canonical examples). This system discussed here attempts to address the apparent dichotomy between “compositional” approaches based on the behavior of pre-designed materials and “environmental” approaches that explore a context. These views have distinct discourses; in the current UK Research Excellence Framework “Sound Art” falls within the purview of fine art, “Composition” under performing arts.

The present system sets out from a different perspective. We consider the real space of performance as a unitary volume within which micro-sonic wave activity is ubiquitous. The apparently silent blank canvas of music is illusory, such an anechoic reality even distressing. Such a view echoes Ingold's observations on soundscape:

... neither sound nor light, strictly speaking, can be an object of our perception. Sound is not what we hear, any more than light is what we see. The scaping of things - that is, their surface conformation - is revealed to us thanks to their illumination. When we look around on a fine day, we see a landscape bathed in sunlight, not a lightscape. Likewise, listening to our surroundings, we do not hear a soundscape. For sound, I would argue, is not the object but the medium of our perception. It is what we hear in. (Ingold 2007, 11)

In his early work on sound, Bill Viola proposed a taxonomy of sonic behaviors, likewise developed from an analogy with light:

A partial list of some of the most basic physical phenomena studied by the acousticians reads like a set of mystical visions of nature:

Refraction ...  
 Diffraction ...  
 Reflection ...  
 Interference ...  
 Resonance ...  
 Sympathetic Vibration ...

Each of these phenomena evokes wonder, even after their scientific representations have been rationally understood. [...] The processes of contemporary media systems are latent in the laws of nature – they have existed in various forms since the beginning of history. (Viola 2013, 41-2).

Figure 1: interference phenomena exhibited by the present wavespace system

The work presented here was developed for one of a sequence of compositions exploring wave phenomena in situated sound. It investigates the use of interference phenomena (fig. 1); others explore refraction and diffraction. Reflection plays a role in all three, as a key component in defining the relationship between space and activity.

We take a wave-based approach to modeling activity within the space. The potential complexity of even aurally trivial musical constructs presents a challenge. Instead of attempting to consider an intractable number of relationships we approach this complexity by looking at the behavior of the gradients and interference patterns generated by the musical material-generating agents that inhabit the space. In this respect, meteorology perhaps provides an analogy; a tornado is not an external event projected into a neutral space, but a product of dynamics within the environment itself. Nevertheless, in the domain of human activity it is best understood and responded to as an autonomous entity with its

own behavior. We might think of the process presented here as second-order sonification.

We suggest that an important component of musical composition is the remapping of materials and phenomena between different modes of representation – from aural (the sonic imagination) to symbolic (notation) to physical (working at the piano), for example. The present system maintains multiple views of its space: representations of its “real”, virtual/mathematical and symbolic or eventual state.

## Technical Description

### Implementation

In this implementation the performer uses a metatrumpet – a microcontroller-extended instrument that communicates its internal and external soundworlds and all physical activity to the computer via Bluetooth and radio. The system software is written in C++, using Max/MSP as interface and sound engine; they communicate using the UDP-based OSC protocol.

### Wave space and performance space – a double bind

The system architecture incorporates three parallel spaces: a virtual wavespace based on a graphical model (maintained in the C++ programme), a symbolic space using CMMR-like representations (quantized to semitones and in time) and the performance space where sounds are played and heard in the physical world (both handled in Max/MSP) (fig. 2).

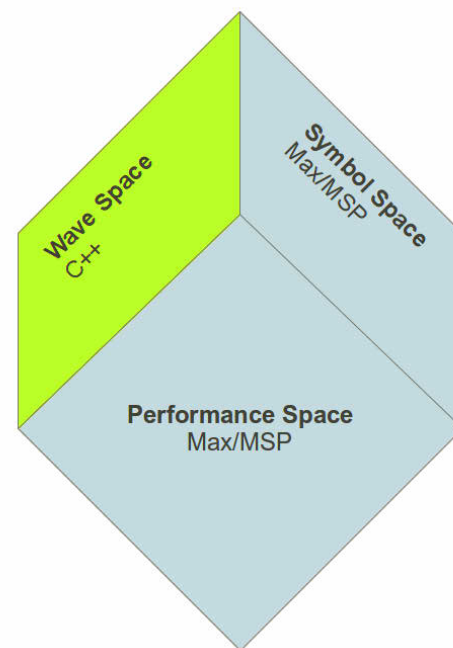

Figure 2: The three parallel spaces can be metaphorised geometrically as three orthogonal planes; navigation in one plane does not affect navigation in the other two, but all three are affected by the dynamics of the system

The performer initiates wave-generating agents. These are singularities in the wave-field - effectively beacons radiating sine waves. The wave behavior of each agent is initialized with values of initial position, frequency, speed of sound and spatial attenuation. Associating speed and attenuation with each individual agent allows for distortions of the space; different agents might find themselves in media through which sound propagates at different speeds. This also permits the effective representation of nonlinear spaces much larger than the actual performance space - large but bounded acoustic spaces within which interference artifacts fall within the range of human hearing. The agent's position is recalculated at every time step, and can be fixed, periodical, rule-based or learned (fig. 3). A repulsive force of proximity prevents terminal convergence. Once initialized, an agent generates one or more sine waves for the duration of its existence. In the initial model, agents are active or not. For reasons of practicality, the model is a steady state approximation. The field is conservative; it has no memory. If an agent is destroyed, all its effects immediately disappear from the space.

```
struct wave{
    float amplitude; //The starting amplitude of the emitted
    wave
    float xpos;      //The x,y positions of the agent
    float ypos;      //...
    float pointvelocity; //The agent's velocity through space
    float omega;     //The emitted wave's angular velocity
    float beta;      //The emitted wave's spacial attenuation
    float learn;     //The agent's learning aggressiveness
    float contr;     //The agent's estimated contribution...
    float control;   //...and in the previous timestep, for
    comparison
    float angle;     //The agent's spatial direction
    bool dominant;   //The agent's state: is it in the most
    harmonic pair?
};
```

Figure 3: C++ data struct for each wave-emitting/-listening agent

At each system time step we know the phase dependent contribution of each agent to the resultant signal at each point in space. In the initial model, system speed is 1 KHz, and the dimensions of the wavespace 256 \* 256 points. Interference patterns within a space are perceived clearly when the dimensions of that space are an order of magnitude above the wavelengths in question. If we assume the scale of a typical performance space to be of the order of 10m, this grid allows for the representation of signals within the range of human hearing - wavelengths of the order of 1m. A balance of precision and computability is particularly critical in a real-time system servicing streams of audio output.

### Sound production

The total wavespace field is calculated by summing the contribution from each agent at each point. Identifying areas

of interest - loci of active interference and potentially emergent behavior - requires deconstructing intuitive understandings. The wavespace itself is indifferent. Initial strategies included looking for peaks in the image derivative - effectively high pass filtering - and edge detection. Both produced indiscriminate amounts of data and proved computationally expensive. The strategy adopted is to identify points of maximum interference by looking at the difference between the scalar sum and the vector sum of the contributing waveforms.

Figure 4 shows the gradients of interference produced by three agents in such a space, and the point of perceived maximum interference calculated as described above.

Figure 4: Three agents in wavespace (1-3) and the point of maximum perceived interference (P)

Interference in this sense is result of phase differences between sinusoids. Another less formal understanding of interference might entail the production of additional noise or artifacts. This is an embodied phenomenon. In the case of hearing, for example, modulation artifacts are a function of the response of the basilar membrane (Moore 2002).

Having localized the point of maximum interference, a hypothetical sound is produced by taking the weighting the various agent audio signals by values stored in a matrix that represent their estimation of their contribution at that point. This data is valid for one wavespace timestep (1ms). The audio stream is subsequently filtered at timestep frequency to mitigate windowing artifacts.

We consider this signal as being emitted radially by the maximum as a point source in wavespace. This sound is never heard directly. In keeping with our embodied understanding of interference, the beacon agents also become listeners and performers in performance space. We then hear the combination of their listenings to the combined reflected

signal, which now themselves exhibit interference due to their phase displacements. The agents are dynamically located in physical space using IRCAM's *Spat* spatializing application within Max/MSP (<http://support.ircam.fr/docs/spat/3.0/spat-3-intro/co/overview.html>).

This information is sent via OSC to the agent's Max/MSP avatar. The audio stream of each agent is constructed by additive synthesis in Max/MSP from the discrete frequency spectrum. It is then buffered to maintain a stable audio stream. It is delayed and attenuated according to its position in wavespace and its local speed of sound. In addition to the frequency/amplitude/phase data representing the point source signal, the performance space is informed of the positions of the other agents and of the maximum. Before synthesis, the agent can make certain musical decisions. In particular, frequency addition artifacts above the range of human hearing (c. 20 KHz) are transposed down to become audible. This initiates a recursive exchange between wavespace and performance space through which increasingly complex sounds can accumulate.

### Accumulating agency

In an early iteration of the system, agent position is determined dynamically by a fixed velocity and a direction of motivation towards the point of maximum interference. A dance develops as agents track the maximum point-source, the location of which is in turn determined by the agents' position. Quasi-oscillation, temporary attractors, reflections, line-following, convergence/divergence, and leaps through space all occur. The latter is not just a function of the bounded wavespace. The real performance space it reflects is also bounded, and such events are therefore considered to be of potential musical-structural significance. Figure 5 shows the movements of three agents and the point of maximum perceived interference for the 56 timesteps leading to the positions shown in Fig. 4.

Figure 5: movement of three agents and point of maximum perceived interference through 56 timesteps preceeding fig. 4

**Microevolution.** A more advanced system is developed where a dynamic number of agents  $N$  navigate the space, and the system judges harmonic relationships between pairs of agents in an  $N \times N$  matrix. The position of the smallest element in this matrix indicates the pair of agents with the strongest harmonic relationship. In a reflection of the bio-evolutionary paradigm, the agents which are not part of this pair reproduce imperfectly and are destroyed, creating imperfect re-initializations of themselves on destruction. Consistent with the spatial model, the degree of mutation is dependent on the proximity of the agent to the point of maximum interference, representing information loss. After successive generations, a different set of two agents will exhibit a stronger relationship, and the set of agents which reproduce will change accordingly. Each agent continues to have a behavior dictated by both the initializing conditions outlined above, and learned behavior (controlling agents' own frequency and direction of spatial movement) maximizing their contribution to the point of maximum interference. The aggressiveness of the learning algorithm is itself an initialized parameter. Agents within the harmonic relationship are understood as changing their behavior whilst agents outside the harmonic relationship change their nature.

**Polyphonic rhythm.** The performed sounds of each agent are subject to a further thresholding process. Agents calculate their own contribution to the sound perceived at the maximum point source by comparing the interference intensity at that point with and without their contribution.

They become active as performers only when this contribution exceeds a threshold – that is, the sound of each agent is turned on and off with a rhythm of variable linearity with windows of periodicity. This creates a polyrhythmic fabric, each strand of which is related to the virtual maximum. The texture can be inverted – transformed to its negative by reversing the threshold test. A challenge in music systems with any degree of automation is to generate the multiple levels of structure found in art music. The system again analyses the relationships between individual agents as pairs, but this time looking for convergence in audial performance space. When both audio streams of a pair of agents converge, giving out a 'drone', a timer is initialized; after a fixed time period, both agents are silenced in performance space. However, they continue to operate in both the wave and symbol spaces, which under the micro- and macro-evolutionary paradigms outlined eventually cause the pair of agents to exhibit different audial-spatial behavior, and their inaudible audio streams diverge. Under these conditions, the audio streams of the two agents are restored to performance space, again becoming audible to the performer (fig. 6).

Figure 6: Thresholding behavior of three agents over time

## Macroevolution – symbolic representation

A third parallel space maintains symbolic representations of performance activity. Streams of sound output, synthesized and live, are analyzed in terms of pitch and rhythm. In both domains this constitutes a process of re-representation and categorization roughly analogous to human cognitive behavior; the point here is not anthro-verisimilitude but process architecture. Perceived pitch is quantized to semitones, rhythm to a 50 ms. grid. Inevitably these processes lead to loss of precision, of information, but they allow for the apprehension of relationships on other levels. The aggregate wavespace output is then analyzed in terms of harmonicity, density of behavior (a measure of number of events perceived over time), “noisiness” (signal-derived value) and stability of amplitude. The rhythmic profile of individual streams are compared by searching for a lowest common denominator – an additive pulse – and looking for matches or complementarity.

Initial threshold values are set for these parameters together with a global coefficient of surprise. Principal Component Analysis is used to produce values representing the balance of factors in the current state. Symbol space directs change in wavespace under two kinds of condition:

- when a subset of parameter thresholds is exceeded
- when the performer triggers a change. In this case, symbol space learns the current PCA state. When the same PCA state recurs (within a given tolerance), symbol space will subsequently trigger the same changes autonomously. PCA thus represents a higher-level representation, less dependent on specific detail of behavior. In this way a repertoire of formally salient states evolves through interaction with the performer.

The changes sent from symbol space to wavespace are distributed among agents by the main loop – effectively a super-agent. They relate to the following properties:

- number of agents: the population may be forced to multiply or divide
- frequency bands: the potential frequency space inhabited by each agent (initially 20-20,000 Hz) may be divided into separate bands, such that the agents are distributed among bands of varying width and distance.
- range and distribution of speeds of sound
- triggering threshold
- repertoire of wavetables (wavetables written from live sound and from wavespace output are added to the initial sine tables)

The system thus evolves over longer time-scales, approximating to formal time in compositional terms, by learning a repertoire of transition states through interaction with the performer.

## The performed space

The live performer is incorporated through performance space. FFT data is passed to wavespace where the performer appears as an agent among others, contributing to the aggregate interference pattern. This is captured by a

microphone at the position of the performer, such that the performed sound of the agents as heard by the performer also figures in this stream. Clearly the performer is not as free to move in wavespace (and doesn’t have the mental capacity to calculate interference maxima). Instead, motion data from the metatrumpet directs both movement in virtual space and the positioning of sound in performance space. The performer controls the range of frequency components to be passed. In a four-band implementation, for example, one might select components 9-12 to avoid the perceived pitch and its low integer multiples, focusing the system’s attention on the activity of higher partials. To facilitate calculation and avoid additional artifacts (from the arbitrary relationship of table length to frequency), a cycle at the lowest perceived frequency is written into a wavetable.

The performer can work with current tendencies, attempting to counter or encourage them, trigger new agents directly, or mark a current state as a moment of transition in symbol space.

## Further Developments

Our intention is to enhance the relationship between virtual wavespace and actual performance space by incorporating an acoustic space-tracing algorithm (Dokmaniç et al, 2013). This impulse response-based technique can be incorporated both in musical terms, by allowing the perceived interference patterns to evolve from a single impulse, and technologically, in that the necessary microphones already form part of the system. Wavespace precision will be unchanged, but the representation can be mapped nonlinearly onto the physical space.

Agents will be empowered to search their own perceived spectrum, to select and transpose series of higher partials that contribute a greater range of color to the whole.

The performer will be able to mark a state as stable as well as transitional. If the potential for any of the evolving repertoire of stable states is perceived in symbol space, wavespace will be encouraged in this direction.

A predictive function will be incorporated in symbol space, in the hope of enhancing the measure of novelty. It will learn by correlation with the performer’s real-time decisions.

## Conclusion

The re-representing of behavior across modal boundaries is characteristic of Western art music of many kinds (Impett, 2009). Indeed, we could understand its historical development as being the incremental and technological exploration of this possibility. Polyphony – a complex system which cannot be fully resolved or reduced (unlike, say a simple melody-and-bass structure) – is the most characteristic property of the last thousand years of art music. The kind of cross-modal interaction explored here allows for the emergence of potential structure on multiple levels and their interaction to generate a complex, compound architecture in which detail on one level relates to form on another. We attempt to create a dimensionality of engagement (of expectation, of analysis, of interpretation) higher than that of purely algorithmic or performer-driven systems. Looking at interference and convergence provides a way of grasping the state of a

complex system and deriving understanding of its potential architecture.

This system can be tuned to the tastes of the musician; it is replicable but not falsifiable. Rather than invalidating aesthetic models as knowledge-producing environments, this obliges us to confront the role of the subject in knowledge production. The apprehending subject is part of the knowledge producing system; production and apprehension become inseparable. A-Life models are used to model societies, cultures, populations and complex systems, but rarely to understand the individual. This may be partly historical, in contradistinction to GOFAI for which the implicit paradigm was perhaps a cartoon of human intelligence. We cannot avoid the role of the subject, however, particularly as such open systems present behavior that cannot be represented in its entirety. In exploring the nature of this new kind of knowledge, Delanda describes their behaviors as singularities in a *space of potential* (Delanda 2011, 18).

This work is part of a wider theoretical project, the *work-without-content*. It takes its cue from Giorgio Agamben's observation that in a culture of infinite difference, of the right to expression in unique individual languages, the common experience on which cultural exchange is possible becomes the confronting of the blank page. He describes the instantiation of such work as giving form to potentiality (Agamben 1999). Here the material derives entirely from the relationship of performer and space.

What is the relationship between the subject as pilot of the system and subject as co-agent? The situation can be characterized in terms of power and rules; it is effectively a legal question. We can look to Agamben once more. He considers the role of the sovereign, the individual in relation to which laws obtain, and yet who may stand outside them. He can be assassinated, but not condemned to death. Likewise his *homo sacer*, the outlawed subject whom the state will not kill but another individual may choose to (Agamben 1998). Sovereign power or *homo sacer*, the rules and behavior of a system such as this produces knowledge – if the production of truths is how we understand the function of art (Badiou 2001, 41-57) – only by incorporating such a subject.

There is another important aspect of emergent knowledge-production - an idea that science, in turn, might take from critical theory. Such knowledge is experiential and situated, it denies commodification and resists attempts at repetition and falsification. In this respect, music might be seen to provide a model for the new knowledge. Meanwhile the commodification of culture proceeds unabated. Science has built for itself a position of immense power and responsibility – effectively a sovereign power, in fact, with which it can validate and rewrite the conditions for knowledge. It is important that the sciences of the artificial look at the nature of the new kinds of knowledge they generate and reflect them back to culture.

# Programming the Assembly of Inorganic Nanomaterials Using Networked Chemical Reactions

Leroy Cronin, School of Chemistry, WestCHEM, The University of Glasgow, Glasgow, G12 8QQ, UK.

Email: [Lee.cronin@glasgow.ac.uk](mailto:Lee.cronin@glasgow.ac.uk); web: <http://www.croninlab.com>

**Keywords:** programmable nanomaterials; inorganic self assembly; inorganic reaction networks; chemical synthesis within 3d printed reactionware; programmable self assembly; emergent nanosystems

Traditionally much of nanochemical synthesis and self-assembly and transformations have been done in one pot reaction systems whereby reagents are added and the reaction conditions are controlled in terms of temperature, solvent, atmosphere and pressure. Although this general approach has been incredibly successful for the bottom up assembly of nanomaterials, the manipulation of programming of complex nanomaterials via reaction networks and the development of systems showing emergent properties require a fundamentally new approach, see Figures 1 and 2.

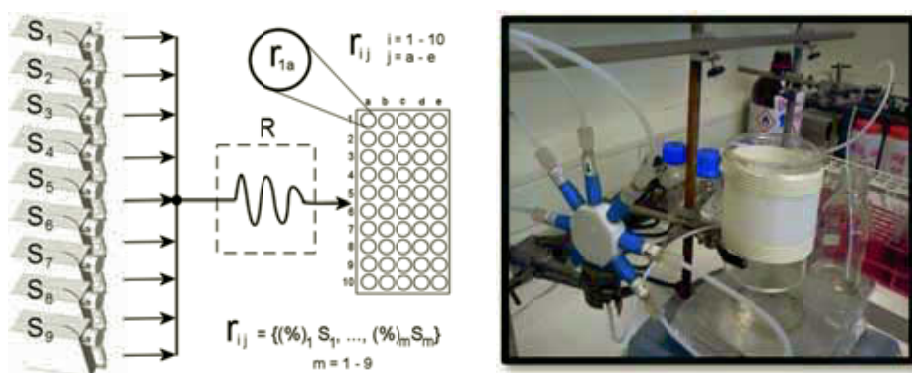

Figure 1. LEFT shows a schematic of the reaction array that can be set up by the continuous flow of reagent inputs ( $S_1$ - $S_9$ ) and the reaction array  $r_{ij}$  that results from the screening of the inputs against each other. RIGHT shows a photograph of the set up.

Figure 2. RIGHT shows a schematic of the networked reactor array (from reagent inputs  $S_n$ ) where different reactions  $R_n$  can be 'networked' or interconnected at different times during the process. RIGHT shows a photograph of the set up.

In this contribution I will outline our recent efforts, investigating the self-assembly and self-organization of inorganic nano molecules and the engineering of complex systems and reaction networks that lead to the emergence of system-level behaviours of interacting nanomolecules. To do achieve this we have developed new reaction techniques to control the assembly of nanoscale molecular metal oxide clusters, some of the largest non-biological molecules known, as well as new physical techniques e.g. the development of new cryospray and variable temperature mass spectrometry (for the elucidation of reaction mechanism and the observation of highly reactive intermediates). Ultimately our aim is to develop minimal inorganic systems capable of evolution, engineering materials with complex and emergent behaviours, as well as the development of new reaction formats for complex and novel chemistry e.g. flow systems and 3D-printing[1-5].

## Abstract

We study a model of multi-legged catalytic molecular walkers that abstract a class of recently developed synthetic molecular motors. We focus on their kinetics of release of catalytic product, delineating the influence of chemical kinetic parameters, geometric configuration, loss from surface, and bulk kinetics. We show that such walkers can achieve a uniform rate of release over long time scales, which can be exploited in applications.

**ECAL Topics:** Molecular Motors; DNA Computing; Applications in Nanotechnology, Computable Matter, or Medicine.

## Introduction

Nanoscale objects are subject to random Brownian motion that leads to undirected diffusive transport. Nanoscale systems that require more precise control over the transport of materials and information must expend energy in some form to bias the random molecular motion in useful directions. A *molecular motor* is a nanoscale device capable of transforming chemical free energy into useful work and directed motion, and can function as a cargo transport device allowing superdiffusive transport of materials. Natural molecular motors play an important role in critical biological processes in the cell and are the source of most forms of motion in living beings (Schliwa and Woehlke, 2003; Vale and Milligan, 2000; Phillips et al., 2013).

In addition to naturally occurring molecular motors, several synthetic molecular motors have been designed recently (Yin et al., 2004; Bath and Turberfield, 2007; Muscat et al., 2011; Wickham et al., 2012; Shin and Pierce, 2004; Venkataraman et al., 2007; Omabegho et al., 2009; von Delius et al., 2010; Kay et al., 2007). We have synthesized catalytic DNA-based walkers called *molecular spiders* (Pei et al., 2006). A molecular spider has a rigid body and several flexible enzymatic legs that attach to and modify substrate DNA molecules (Figure 2a). When we first reported molecular spiders, we were keen to explore their motive properties and subsequently we experimentally demonstrated their ability to follow patterned nanoscale tracks of

DNA substrate molecules (Lund et al., 2010). Our mathematical modelling efforts similarly were focused on characterizing the spiders' walking gaits, such as predicting their ability to do organized mechanical work in opposition to an external force (which we hope experimentally to validate in the near future). On the other hand, in the original study we also observed excellent chemical processivity of the spiders; in one assay spiders and their substrates were randomly deposited in a matrix in a 1:3800 ratio, and the spiders cleaved nearly all substrates before dissociating from the matrix (Figure 1). We noted the nearly linear rate of substrate cleavage in this case, but this observation has not been explained or exploited.

Figure 1: Data from a surface-plasmon resonance experiment. Four-legged spiders were released into a 2½D dextran matrix displaying the substrates. There were 3800 substrates to each spider, and over the course of the assay the spiders cleaved 100% of the substrate offered, exhibiting an initial linear increase in the amount of released product. (After Pei et al. (2006).)

In separate studies, we have shown that the deoxyribozyme chemistry of the spiders' legs is compatible with actuation, such as the release of small molecules (Kolpashchikov and Stojanovic, 2005; Yashin et al., 2007), as well as controllable by both oligonucleotides (Stojanovic et al., 2002) and small-molecule ligands (Stojanovic and Kolpashchikov, 2004), including via complex decision-

making molecular logic (Macdonald et al., 2006). Therefore, the sustained nearly uniform rate of release from a matrix, mediated by activated spiders (or other multivalent catalytic walker chemistries), may have promise in drug delivery. Indeed, achieving zero-order kinetics of drug release is a long-standing but difficult goal of pharmacokinetics (Siepmann et al., 1999; Siepmann and Peppas, 2000; Gupta and Kumar, 2000; Agrawal et al., 2006; Kim, 1995); a new study shows the use of nanoparticles to approximate it (Gu et al., 2013).

Here we numerically study the product-release properties of molecular spiders and show that:

1. walker-mediated release of product can be an effective tool for achieving a uniform rate of release over long time scales;
2. catalytic bias is essential for the operation of this mechanism;
3. catalytic bias is an effective tool for regulation of release rate;
4. multivalency is a practical mechanism for overcoming the problem of dissociation (confirming the results of Samii et al. (2010); Olah and Stefanovic (2013)).

The results provide a first guide to the vast parameter space available to the designers of potential molecular-spider-based drug delivery vehicles.

## Molecular Spiders and Their Models

In this paper we use a model that describes the motion of multipedal enzymatic walkers as they move over and modify chemical sites arranged as arbitrary 2D tacks and patterns (Figure 2b). A walker has a rigid body with attachment points for  $k \geq 2$  identical, flexibly tethered legs. Each leg has a reactive site at its foot that can reversibly bind to and enzymatically modify surface-bound chemical sites from a substrate species into a product species. As a walker moves over a surface of substrate sites, the enzymatic actions of the legs leave behind a trail of modified product sites. These modified sites create an asymmetrical distribution of substrates around the walker. When the leg-product binding is weaker than the leg-substrate binding, this local substrate asymmetry can bias the motion of the walker away from previously visited areas and towards unvisited sites, causing an otherwise unbiased symmetric walker to move superdiffusively. Thus, the walkers transform the chemical free energy in the surface sites into directional motion and can do ordered work in opposition to an external load force, hence they are a new type of molecular motor, useful for directional transport in nanoscale systems.

We formulate the model as a continuous-time Markov process that describes the stochastic motion of the walker as a sequence of transitions between discrete chemical states. Each walker state is described by the chemical state of the

surface sites (substrate or product) and the current set of sites where a leg is attached. The transitions from state to state correspond to the discrete chemical actions of legs binding to sites, unbinding from sites, or enzymatically modifying attached substrate sites to products. From any particular chemical state of the walker legs, each individual chemical action is independent of the previous state of the walker and of the chemical state of the other legs. In other words, the legs are not kinetically coupled. They are, however, mechanically constrained by their connection to a common body.

We use Monte Carlo algorithms to simulate the motion of multivalent random walkers as they move over a track of substrate molecules (Figure 2c). We find that when the rate of substrate catalysis is much slower than the rate of product detachment, the walkers (on average) move superdiffusively away from the origin. Furthermore, our model is designed to quantify the effect of a constant load force opposing the walker motion. We have found (Olah and Stefanovic, 2013) that the superdiffusive motion of the walker persists even under moderate loads of  $\leq 2.0$  pN, for legs with maximum extension length  $\ell = 12.5$  nm ( $2.5 \times$  the lattice pitch). Hence, the walkers are capable of transforming the chemical free energy of substrate molecules into directed transport and ordered mechanical work. We designed the model to investigate a minimal set of mechanical and kinetic features that are necessary to transform the otherwise unbiased diffusive motion of multipedal enzymatic walkers into directional, superdiffusive motion useful for nanoscale cargo transport: even though a walker's legs are identical, unoriented, uncoordinated, and unconstrained other than the passive constraint implied by their connection to a common body, nonetheless we find that these simple geometric constraints on the legs combined with the kinetic bias in the direction of unvisited substrates suffice to generate superdiffusive motion, even when that motion is opposed by an external load force.

While this model provides good physical detail, it can be computationally rather demanding, which justifies mathematical models of molecular spiders at greater levels of abstraction, for instance, simplifying the chemical kinetics and the geometry of the walker and its track. Antal and collaborators studied a single simplified spider on a one-dimensional track (Antal et al., 2007; Antal and Krapivsky, 2007), showing that a difference in residence time between substrates and products, in conjunction with the presence of multiple legs, biases the motion towards fresh substrates when the spider is on a boundary between substrates and products. We showed that this bias makes spiders move superdiffusively for long periods of time (Semenov et al. (2011a). Samii et al. investigated various gaits and numbers of legs (Samii et al., 2010, 2011), emphasizing the possibility of detachment from a 1D track. We studied the behavior of multiple spiders continuously released onto a 1D track (Semenov et al., 2011b, 2012) from a point source. Re-

Figure 2: The multivalent random walker model describes the motion of multipedal walkers acting as molecular motors as they move over tracks of surface-bound substrate fuel. (a) The model is inspired by a type of DNA nanowalker called a *molecular spider* that has a rigid, inert body and several enzymatic legs that can attach to and cleave complementary DNA substrates arrayed as nanoscale tracks. (b) The model describes the 2D motion of molecular-spider-like walkers. We assume the mechanical motion of the body and of its legs comes to an equilibrium in between chemical steps, allowing us to describe the attachment likelihood over the set of local feasible attachment sites. (c) Under appropriate kinetic biases between product and substrate sites, the walkers move superdiffusively in the transient, even when their motion is opposed by a conservative load force.

lated to the present topic, Antal and Krapivsky evaluated the diffusion constant and the amplitude describing the asymptotic behavior of the number of visited sites (i.e., released products) for a single simplified spider on an infinite square lattice (Antal and Krapivsky, 2012).

### Model Definition

The formal model we assume here is a minor simplification of our general model, described in detail in Olah and Stefanovic (2013). In the context of a product-release application, as opposed to transport, we need not be concerned with external forces, and therefore we can set them to zero, which makes all feasible body positions equally likely; this eliminates the need for expensive equilibrium Monte Carlo computations in the inner loop of the simulation. Further, we approximate the region of feasible sites (Figure 2(b)) as the intersection of circles of radius  $2\ell$  around all current attachment points; this eliminates the need for elaborate computational geometry calculations. Finally, we assume all sites within the feasible region are equally likely to be chosen as the next attachment point for the leg that is moving.

The chemical reaction scheme is

showing the essentially irreversible binding of an enzymatic leg  $L$  to a substrate  $S$  to form a complex  $LS$ , which leads irreversibly to the cleavage of the surface-bound substrate into two product parts. The scheme only shows the part  $P$  that remains bound to the surface; the other is released into

the environment, and is in fact the product part of interest in applications. The second reaction describes the fleeting, reversible, binding of a leg to the surface-bound products. The rate  $r$  encapsulates both the catalytic cleavage of the substrate and the subsequent dissociation of the leg from the products. The rate of dissociation from products is set to 1, i.e., our model is dimensionless.

We use kinetic Monte Carlo simulation (Bortz et al., 1975; Voter, 2007) to generate trajectories of the model for various parameter combinations. The implementation techniques we use are standard; of note, the results in this paper were generated with a highly customizable representation written in Haskell.

### Results

We have obtained simulation results for the following product release scenario. The walking surface contains 40,000 sites in a  $200 \times 200$  box in a 2D square lattice, initially consisting entirely of substrates. One hundred walkers are deposited uniformly at random onto the surface, each walker having one leg attached to a substrate and the remaining legs free. This gives a 1:400 ratio of walkers to substrates, a scaled-down version of the laboratory experiments. The walkers are followed as they move around the box until all substrates have been turned into products.

We observe the number of products on the surface, which is equal to the number of products released into the surrounding medium. We do not model the diffusion of released products into the environment. To control for the possibility of walker dissociation, we also observe the number of walkers left on the surface.

We study the effects of spider geometry by varying the

number of legs from 1 to 6. In the plots that follow, only 2-, 4-, and 6-legged walkers are shown, for clarity. One-legged walkers dissociate from the surface immediately; 3- and 5-legged walkers have intermediate behaviors as expected. We also vary the leg length. We use the length  $\ell$  equal to 2.5 times the lattice pitch as our baseline, and also consider what happens if the legs are much shorter,  $\ell = 1$ , or longer,  $\ell = 5$ .

We study the effects of different chemical kinetics by varying the catalytic rate parameter  $r$ , i.e., the degree of residence-time bias between substrates and products. We also vary the binding rate parameters  $k_S^+$  and  $k_P^+$ .

### Baseline observations

Figure 3: Number of products released as a function of time for 2-, 4-, and 6-legged walkers, with  $r = 0.01$ ,  $k_P^+ = 1000.0$ ,  $k_S^+ = 1000.0$ , and  $\ell = 2.5$ .

Shown in Figure 3 are plots for product release using a baseline set of parameter values (Olah and Stefanovic, 2013),  $r = 0.01$ ,  $k_P^+ = 1000.0$ ,  $k_S^+ = 1000.0$ ,  $\ell = 2.5$ , and for three different leg configurations, 2-, 4-, and 6-legged.

Consider the product release curve for the four-legged walkers (green). It rises essentially linearly for a long time before tapering off towards the ceiling of 40,000 as eventually all sites are turned into products. In this respect the model captures the empirical observations from Figure 1. Also drawn in green are two theoretical curves. The dashed line corresponds to exactly linear product release at a rate equal to the initial rate for the walker (zero-order kinetics). Note that the initial rate of product release for the walker is easily seen to be the product of the substrate catalysis-dissociation rate, which we are calling  $r$ , and the number of legs, since almost immediately upon deposition all legs are on substrates. The dotted line corresponds to an exponential decay that starts with an initial rate equal to the walker's, and tends to the same asymptotic value (first-order kinetics). The observed curve is bracketted between the two theoretical curves, adhering more closely to zero-order kinetics.

Analogous families of curves are shown for two-legged

walkers (red) and six-legged walkers (blue). The initial slope is proportional to the number of legs because each leg is an independent enzyme, and initially all legs quickly find a substrate to bind to. Interestingly, the adherence of the observed kinetics to zero-order kinetics lasts longer for  $k = 2$  walkers than for walkers with more legs.

### Varying the catalysis kinetics

Here we show the effects of varying the parameter  $r$ , keeping the binding kinetics fixed at the value  $k_P^+ = 1000.0$ ,  $k_S^+ = 1000.0$ , which means that binding is very fast and there is no binding preference between substrates and products. Figures 4(a)–(c) display  $r = 0.001, 0.1, 1.0$ , in addition to  $r = 0.01$  from Figure 3.

The initial rate of product release varies in proportion to  $r$ , as expected because  $r$  is the hopping rate for legs on substrates. The overall time to completion grows roughly in inverse proportion to  $r$ , therefore the four plots are accordingly scaled, allowing us to observe the changes in the shapes of the curves. The adherence of the observed product release curve to the zero-order kinetics theoretical curve improves when  $r$  is decreased to 0.001 and it worsens when  $r$  is increased. When  $r$  reaches unity, and the residence-time bias is lost, product release becomes slower and less uniform even than first-order kinetics; furthermore, there is an inversion effect for the number of legs—even though initial product release rates are higher for greater  $k$ , eventually these walkers fall behind two-legged ones.

### Varying the binding kinetics

In these simulations, we keep the catalysis fixed at the baseline value of  $r = 0.01$  but we vary the binding kinetics, i.e., the on-rates  $k_P^+$  and  $k_S^+$ .

In Figure 5, we decrease the on-rate for substrates tenfold, so that a leg is effectively repelled from substrates. Comparing with the baseline results of Figure 3, while the initial rates (dominated by catalytic cleavage) are not affected, the product release curves diverge from zero-order kinetics much sooner, presumably because the walkers are diverted from exploration of fresh substrates and find themselves diffusing in their own local seas of product. If we also decrease the on-rate for products we recover the original behavior as in Figure 3 (we reserve for future study the effects of decreasing the two on-rates further towards the catalysis rate, outside of the regime of rates measured for deoxyribozyme walkers).

### Varying the leg length

Keeping the chemical kinetics parameters at the baseline, we now vary the geometry of the walker, namely its leg length. The baseline leg length  $\ell = 2.5$  corresponds to the molecular spiders used in laboratory experiments, Figure 3. If the legs are made much shorter, as in Figure 6(a), spiders with

too many legs become slower. A detached leg is too constrained by the maximum distance from the remaining legs' attachment points, and it is impeded from finding fresh substrates. Thus the product release of the 4-legged walker is slower than first-order kinetics, but for the 6-legged walker it is slowed down to even less than the 2-legged walkers' pace.

On the other hand, if the legs are made longer, as in Figure 6(b), a moving leg has a greater probability of finding a substrate when the walker is on the edge of the patch it has grazed, hence we observe better adherence to zero-order product release kinetics.

## Dissociation

Since in our walker model the legs are uncoordinated, it is possible for all legs of a walker to become detached. When that happens, the walker is removed from the simulation—indeed in control experiments Pei et al. (2006) we had measured the rates at which dissociation happened with molecular spiders. However, in the model as well as in the laboratory, dissociation is a rare event for the chosen baseline kinetics. In Figure 7 we show the number of walkers present, initially 100. Dissociation is a significant phenomenon only for two-legged walkers; for walkers with more legs, simultaneous detachment is unlikely. Thus, dissociation is not the primary cause of the drop-off in the product release rate; rather increased dissociation is a consequence of the decay into diffusion over products as each walker's local area of products grows, or as the neighboring areas merge: legs on products detach much more frequently and thus the rate at which dissociation events occur is much greater.

## Discussion

Let us consider the model of Equation 1 as if occurring in bulk solution, where the initial number of substrate molecules is the same as the initial number of sites (40,000), and the initial number of enzymes is equal to the total number of spiders' legs (200 for two-legged spiders). As shown in Figure 8(a), for  $r = 0.01$  bulk release (black curve) is nearly linear. On the other hand, in Figure 8(b) for  $r = 1$  bulk release amounts to exponential decay. Thus, as  $r$  is decreased from 1 towards 0, bulk release improves from first-order kinetics to zero-order kinetics. Spider release is also shown, and it is in both cases slower than the corresponding bulk release. After all, this should be expected from first principles. (1) In a well-mixed solution, all potential substrates are available to the enzyme. With spiders, this is not the case because substrates are a local resource; whenever the spider is diffusing in the sea of products, they are not available at all. (2) Eventually some spiders completely dissociate. These two effects make spider product release less efficient than with the hypothetical bulk solution reaction. Both these effects diminish as  $r$  is decreased from 1 towards 0. This explains why, for small values of  $r$ , product release

by spiders is nearly the same as bulk release, which in turn is nearly linear. Thus, under suitable conditions, spiders are an effective mechanism that allows an enzyme to visit surface-immobilized substrates, yielding almost the same resultant kinetics as in a perfectly mixed volume reaction.

Here we have studied a practically motivated problem: the release of products in a bounded domain by a fixed finite number of walkers. In future work, we will explore the behavior of walkers in an unbounded domain, such as the plane. In this setting, there are known analytical results for ordinary random walkers and for the simplest spider models Antal and Krapivsky (2012), namely that asymptotically  $N(t) \propto \frac{t}{\log t}$ , and we shall examine how the catalysis and the presence of multiple legs affect this behavior. It will be interesting to connect the unbounded-domain behaviors with a more detailed analysis of the bounded-domain cases, including varying how the walkers are initially deposited (different spatial distributions), and considering sources of injection.

In our laboratory we have been developing new approaches to discover the 'transition-to-evolvability' in chemistry. This is because if we can discover or engineer an abiotic system that can evolve (we could define this as an inorganic chemical cell -iCHELL) we might be able to suggest that synthetic biology can exist in many chemical forms, of which the terrestrial biology found on planet earth is one subset. It could even help us establish the idea that evolvability is the key signature that defines living from non-living systems. This problem is rather vast since our aim is to compress a planet sized reaction vessel and a 400 M year run-time into a laboratory over a few years! Not only does this extraordinary problem require new radical chemical approaches[1], it also requires the development of some radical new technological solutions[2-3]. In this talk I will cover both aspects with an emphasis on how some of our new approaches can be applied to both 'inorganic' and 'organic' synthetic biology with a special emphasis on rapid fabrication of systems for synthetic biology that allows the 'plug and play' of synthetic biology in new fluidic formats, see Figure [1-2].

### Abstract

In models of games, the indirect interactions between players, such as body language or knowledge about the other's playstyle, are often omitted. They are, however, a rich source of information in real life, and increase the complexity of possible strategies. In the game of rock-paper-scissors, the simple monitoring of the opponent's move *before* it was played is a sufficient condition to trigger an arms race of detection and misinformation among evolved individuals. The most interesting aspect of those results is that they were obtained by evolving purely chemical reaction networks thanks to an adapted version of the famous NEAT algorithm. More specifically, those individuals were represented as biochemical systems built on the DNA toolbox, a paradigm that allows both easy *in-vitro* implementation and predictive *in-silico* simulation. This guarantees that the specific motives that emerged in this competition would behave identically in a test tube, and thus can be used in a more generic context than the current game.

### Introduction

The game of rock-paper-scissors, while being simple, can actually lead to interesting dynamics when it is played multiple times in a row. In particular, each player will try to “read” their opponents in the hope of getting the upper hand. However, if psychological factors are not taken into account, that is, if players are purely logical, game theory predicts that after a while, the optimal strategy becomes to play randomly with no bias among the three possible moves (Smith, 1993). Variations of the basic rules exist, but are expected to display the same kind of behaviors (from the point of view of game theory) as the classic three moves.

Interestingly, this game can be a good description of many mechanisms ranging from reproductive strategies of some species of lizards (Sinervo and Lively, 1996) or bacteria (Kerr et al., 2002) to oscillations in a gene regulatory circuit (Elowitz and Leibler, 2000). In all cases, there are three possible moves, each strong against another and weak against the remaining one. This usually leads to dynamical behaviors where the different players are constantly invading each other, forming complex spiral structures in two dimensional systems (Kerr et al., 2002; Reichenbach et al., 2007). Even

real life examples, such as the lizard example, display oscillations in population size, with a turnover of approximately six years, based on the field data of (Sinervo and Lively, 1996). Those dynamics may degenerate into a uniform population depending on the initial conditions, or such parameters as the mobility of the players. On the other hand, they may also occur even in a well-mixed system, where there is no spatial compartmentalization to protect diversity, if a given move gets stronger when it is less frequent (Freen and Abraham, 2001) or if the system never stalls, like in the repressilator (Elowitz and Leibler, 2000).

However, all those examples either suppose or require that a given individual will always “play” the same move. Indeed, the lizard will always have the same size and coloration, bacteria the same genotype and genes in the repressilator are not expected to arbitrarily change which target genes they inhibit. From a strategic point of view, more possibilities open when each agent can decide, at each time, which move he wants to put forward. In such a case, some form of knowledge of the opponent becomes necessary in order to infer his probable next move and play accordingly. This knowledge is obtained from two sources: cheating and analysis of the opponent previous moves. “Cheating” here designates the fact of obtaining clues about an opponent from its behavior just prior to the game, not in the negative sense of making a game uninteresting by bypassing the rules. Note that cheating in this sense is both an integral part of most human plays and of biological strategies, and in any way is an essential ingredient of any physically instantiated game. In fact, instantaneous moves and decisions are not possible in a physical world, which means that information is always leaked somehow. This fact was used by the Ishikawa laboratory in Japan to program a robot hand (Namiki et al., 2003) reacting fast enough to hand gestures to be able to always win against a human (video online).

While both cheating and strategic analysis requires significant abilities and are generally associated with intelligent players (or at least, players with intents), we wanted to demonstrate in this paper that purely molecular systems are also capable of intricate strategies, whose complexity can

be comparable to that of real players. Indeed it has been recently demonstrated that Turing universality can be achieved through the sole use of chemical reactions (Magnasco, 1997; Soloveichik et al., 2010; Cardelli, 2011). Moreover, practical bottom-up approaches have been proposed to actually instantiate arbitrary reaction networks (Seelig et al., 2006; Qian and Winfree, 2011). However, experimentally, only relatively simple tasks (equivalent in complexity to those performed by the most basic electronic circuits) have been demonstrated. Even from a theoretical standpoint only quite simple systems have been proposed, very far from the intricacy observed in the case of cellular regulation maps, or even bacterial behaviors.

The individuals we evolved were defined as entities from the DNA toolbox (Montagne et al., 2011), a particular paradigm to define DNA-based computing systems. In particular, we build on a unique feature of the DNA toolbox, which is to couple a generalized experimental strategy for the *in vitro* building of reaction networks to the availability of straightforward (if large, from the point of view of equation solving) quantitative models. These models allows exact mathematical predictions and thus allow to perform both *in vitro* and *in silico* designs in parallel.

Individuals were evolved through an adapted version of NeuroEvolution of Augmenting Topologies (NEAT) (Stanley and Miikkulainen, 2002), dubbed bioNEAT, using a fitness function based on how well they fared in a population-wide tournament. To our surprise, the apparition of a basic memory was not hard, but was almost immediately discarded, as it was not able to compete against cheating. Due to the necessity of having both players in the same well-mixed environment, it was much more efficient for an individual to actually develop a way to monitor the actions of its opponent while hiding its own move. When pushed to the extreme, this strategy produced interesting dynamics where individuals went through multiple moves before the end of the countdown, trying to settle into a winning position, eventually leading to some fashion of oscillatory systems. The mechanisms used for those purpose were interesting in themselves, including concentration comparators or system with multiple levels of activation, giving, through motif mining, insight into the possibilities of the DNA-toolbox. This showed that indeed, the behavior of purely molecular systems, corresponding to a realistic, directly implementable chemistry, can be interpreted in terms of complex strategic planning.

## Related Work and Current Contributions

Our work builds on multiple sources since it mixes design by genetic algorithm with molecular programming. Game theory was also an important source of inspiration, and was useful to check that our evolved individuals are playing in a way that differs from hypothetical “perfect” players.

## Rock-paper-scissors

There are also many previous works related to the game of rock-paper-scissors. However, to the best of our knowledge, they either use individuals which are only capable of playing one move, or link existing dynamics to an instance of the game. The evolution game theory study in (Smith, 1993) is the closest to our work, but lacks the added dimension that comes with dealing with cheating or leak of information (Cook et al., 2012). While DNA-based systems can hardly be described as having any form of intelligence, it is easy to rationalize their behavior as cheating, a very real possibilities among human players that is not taken into account in (Smith, 1993).

## Motif Mining

The idea of using DNA computing to play games has been previously introduced (Macdonald et al., 2008). Finding systems able to play a game is in itself a challenge that leads to developing new structures, and potentially solve issues related to real life problems. However, the use of evolutionary algorithms (Eiben and Smith, 2003) stand as a promising candidate to search for interesting reaction circuits. From the structural point of view, the analysis of the fittest individuals of specific runs revealed common functional motifs, which may help build new systems. This is the fundamental approach of synthetic biology, in which biological modules are recombined to perform engineered operations (Purnick and Weiss, 2009). In particular, it was interesting to note that, although actual patterns may vary from individuals to individuals, it was possible to classify them into rough generic categories. This could be used to create minimal libraries of structures for dynamic systems, that is, off-the-shelves building blocks like those defined in (Rodrigo et al., 2011). Such libraries would in turn allow the fast and reliable development of complex DNA-based systems. While, in our case, the structures evolved by the algorithm are possibly not generic enough to be useful in any given context, they still have potential applications for the design of a variety of such systems.

## Model

### The DNA toolbox

The DNA toolbox (Montagne et al., 2011; Padirac et al., 2012) is a set of three modules designed to reproduce gene regulation networks dynamics with a simple framework. Those modules, namely activation, autocatalysis and inhibition, use solely DNA strands and enzymes, making both modelization and implementation of systems straightforward (at least when compared to the *in-vivo* lego networks of synthetic biology). DNA sequences have two possible roles: either signal (simply designated as sequences in the following) or templates. The templates are the backbone of DNA toolbox systems, and are used to generate a specific signal

Figure 1: Graphical representation of systems from the DNA toolbox. Nodes represent sequences while arrows represent templates. The Oligator (left) can be mutated into a bistable in two steps. First, an autocatalysis connection  $B$  to  $B$  with an inhibition from  $A$  is added. Then, the activation from  $A$  to  $B$  is removed. Note that those two operations may happen in any order.

from another signal. Specific sequences can also be generated to inhibit a given template. Since they represent the “code”, templates are kept stable over time, and are chemically protected against enzymatic activity that could affect them. Signal sequences, on the other hand, are continuously degraded to keep the system dynamic.

The important feature of the DNA toolbox activatory and inhibitory modules is that they are arbitrarily connectable to each other. The designer of the network freely defines the pattern of interactions by assigning the sequences of the template through Watson-Crick complementarity. For example, a cascade of activation reaction is obtained by mixing a number of bidomain templates such as  $AB$ ,  $BC$  or  $CD$ , where  $A$ ,  $B$ ,  $C$ ,  $D$ , and so on represent orthogonal 11mers. The Oligator from (Montagne et al., 2011), a simple oscillator, is obtained by combining the three templates  $AA$ ,  $AB$  and  $Blaa$  (where  $Iaa$  represent the inhibitor of  $AA$ ). The graph of this system can be seen in Figure 1, left.

One interest of the toolbox in the scope of genetic algorithms is that any modification of the “genome” of an individual (that is, the sequences and templates it is made of, not to be confused with the hypothetical genome their actual DNA strings are encoding) still yields a valid individual (albeit a possibly uninteresting one), and that a wide range of possible behaviors are very few modifications apart. For instance, bioNEAT (see next Section) can jump in two steps from the Oligator (Montagne et al., 2011) to Padirac *et al.*’s bistable system (Padirac et al., 2012), as shown in Figure 1. This helps the algorithm navigating the search space more efficiently, as well as preventing, to some degree, the trap of local optima.

**Individuals and encoding** The individuals we consider are chemical reaction networks playing rock-paper-scissors. Each possible move (rock, paper or scissors) is mapped to a specific chemical species (DNA sequences, more specifically signal sequences from the DNA toolbox). Those species are fixed in advance, so that they are always present. Individuals also have references linking to potential oppo-

Figure 2: Simple cheating individual displaying both direct and indirect monitoring. Nodes in the dashed box are references to the opponent’s sequence (up) or to the clock (right). By default, this individual will play rock ( $R$ ). If its opponent plays rock or paper ( $P$ ), it will update to play the winning move. Note that this individual does not use the clock.

nents’ corresponding sequences. The main goal of this interface is to allow individuals to react to the opponent’s moves and adapt their strategy over time. Finally, all individuals have a reference to a common clock species, giving them a sense of time. An example of individual is shown in Figure 2.

Individuals are pitted against each other in matches made of ten rounds. The beginning of a round is marked by a spike from the clock sequence. At the end of a round, roughly 20 times the clock’s half-life later, an individual’s move is decided by which of its move sequences has the highest concentration. If the two highest or all such concentration are not different by at least a given threshold, the move is considered invalid, granting the victory to the opponent. Individuals can potentially memorize their opponent’s strategy, since there is no reset between rounds.

**Simulations** The simulation itself was kept simple, with a model similar to that of Padirac *et al.*. In particular, this model doesn’t take into account enzyme saturation. This prevents some advanced strategies (since saturating enzymes may be in itself a way to kill one’s opponent, thus winning by default) and allows individuals to grow without limitations, continuously increasing their size. Since enzymatic saturation creates hidden couplings between the nodes (Rondelez, 2012), removing it was taken as a step to insure the readability of the results. Thanks to this, the behavior of the network - and hence the individual’s strategy - is directly encoded by the networks of cross regulations between the nodes, and not by various type of competitive inhibitions acting at a global level. Using this simplified model is also a compromise between computational requirements and pre-

cision, but any observed behavior should be obtainable in real *in-vitro* experiments.

### bioNEAT: NEAT for Reaction Networks

The evolution of individuals was done by using a modified version of NeuroEvolution of Augmenting Topologies (NEAT) (Stanley and Miikkulainen, 2002), adapted to perform with simulated individual networks built using the DNA toolbox paradigm instead of artificial neural networks. The evolution itself was performed through multiple runs and tweaking of the fitness function.

### NEAT

NEAT is a state-of-the-art evolutionary algorithm designed to evolve both the topology and the parameters of neural networks, while keeping them as simple as possible. This is done by starting from very simple individuals, and progressively complexifying them in a competitive process. This is performed through the addition of new nodes and connections, while at the same time modifying the weight of existing ones.

The major strength of NEAT is that it keeps tracks of when specific connections or node were added in the ancestry line. This allows to perform meaningful cross-over: identical elements present in two individuals, are automatically recognized and matched during the creation of a new individual from two parents. Additionally, mismatching elements from the fittest individual are also passed along.

NEAT also performs speciation to protect innovation that could require more than one step to find a new, better solution to the problem at hand. Specifically, the size of a species depends on the average fitness of its individuals, preventing one type of solution to completely invade the population. Moreover, speciation is easily performed, since the history of evolution of individuals is saved, giving a straightforward distance between individuals based on the genes they possess.

### bioNEAT

Due to the initial resemblance between reaction network and artificial neural network, NEAT stands as a relevant option for optimizing toolbox-based systems. In particular, systems from the DNA toolbox have a straightforward edge/node graph representation similar to neural networks: DNA sequences can be directly mapped to nodes, and connections with positive weights are equivalent to activation links. However, the DNA toolbox cannot be directly implemented using the original NEAT for two reasons. Firstly, additional parameters regarding sequences stability and initial concentration must be added. Secondly, negative links targetting nodes must be replaced by inhibitory links targetting arcs. To address these issues, we introduce bioNEAT, a NEAT-derivative that is able to optimize reaction networks.

A first feature of bioNEAT is to allow the GA to not only modify the “weight” of connections (that is, the concentration of DNA template, in our representation), but also the relevant biological parameters (such as the thermodynamical stability of DNA sequences and their initial concentrations). The thermodynamical parameters of the move sequences was fixed to prevent individuals to use extremely stable sequences to saturate the monitoring of their opponents. In the particular case of the experiments described hereafter, we also prevented activations toward the opponent or the clock.

The second feature of bioNEAT addresses the asymmetry between activation and inhibition process that is inherent to the DNA toolbox, and which cannot be modelled as a classic neural networks link with positive and negative weights. While the sign of a neural weight simply encodes the type of the connection and target a node, a DNA toolbox’ inhibitor targets an *edge* (and impact only one of the output from the source node) rather than a node. Moreover, an inhibitor cannot be instantiated without the template it inhibits. As a consequence, bioNEAT protects the addition of an inhibitory connection (and removal of a particular template) during evolution. Then, bioNEAT produces reaction network with inhibitory connections from node to link.

### Fitness Score

Scoring of an individual uses a lexicographic fitness function taking place in two steps. First, the individual has to beat the three most basic possible players, playing respectively only rock, paper or scissors. This ensures that our individuals are able to play all moves, and to play them discerningly. Individuals unable to pass this test are awarded a very small fitness, based on the number of rounds they have won, directing the evolution toward basic strategies. On the other hand, individuals which were able to pass the test are awarded the right to enter the second phase.

The second phase is a simple tournament among all remaining individuals: each of them has to fight each of the others. The fitness is then based on the amount of correct moves made in total. A sample match is shown in Figure 3. Because of this, the evolutionary pressure forces the individuals into an arms race, to be able to defeat as many opponents as possible.

### Results

Results were obtained by evolving individuals in 10 separate runs, always starting from a uniform population of individuals with autocatalysis on the rock sequence (thus playing always rock). A typical run involved 200 generations of a population of 100 individuals. bioNEAT speciation control loop is adjusted to keep the number of species as close as possible to 10. Other relevant parameters are shown in Table 1. Over the course of the experiment, various kind of strategies emerged before getting outdated or integrated into

Figure 3: Two fighting individuals. References to the opponent's nodes are shown in the dashed box. Top: the actual network of those individuals. Bottom: the corresponding behavior over time. The color code for sequences concentration is red for the clock, green for rock, blue for paper and purple for scissors. The individual on the right has a better comparison mechanism than the individual on the left, as shown by the fact that it has the correct move before the match starts. However, the individual on the left uses the clock to fake switching his move from scissors to rock, which coerces its opponent to update its move to paper. Just before the round is validated, the individual on the left changes its move again to scissors, winning each hands.

more complex control systems. However, in our runs, a stable group of species typically appeared after 50 to 100 generations and quickly took over the population until the end of the run. They represent individuals which had developed part or all of the mechanisms explained later in this Section, and the apparent stability was only due to a constant arms race, where individuals kept adding more and more modules, while those who couldn't keep up were discarded. However, since our fitness can only compare individuals among a given generation, its evolution over time does not reflect the global improvement of individuals. This prompted us to perform a post-mortem analysis of our individuals by making the best of each generations of a given run fight each other, highlighting a progressive improvement of our individuals, as shown in Figure 4. In particular, the logarithmic shape of the curve goes well with the idea that the efforts required to overcome one's opponents are greater and greater as the simplest strategies get commonly countered.

### Cheating

The easiest, and thus first strategy evolved is actual cheating. Since they have references to what each other will play, and continuous access to current concentrations, the individuals monitor the action of their opponent and try to play accordingly. A minimal example is shown on Figure 2. Cheating can be of two kinds: either using a direct connection ("if my opponent plays rock, I will play paper"), or an inhibition ("if

### General parameters

|                       |     |
|-----------------------|-----|
| Population size       | 100 |
| Number of generations | 200 |

### Speciation parameters

|                               |                          |
|-------------------------------|--------------------------|
| Targeted number of species    | 10                       |
| NEAT compatibility parameters | $c_1 = c_2 = 1; c_3 = 0$ |
| Initial speciation threshold  | 0.6                      |
| Minimal threshold             | 0.1                      |
| Threshold update $\epsilon$   | 0.03                     |

### Mutation parameters

|                                  |      |
|----------------------------------|------|
| P(Mutation only)                 | 0.25 |
| P(Parameter mutation)            | 0.9  |

| Otherwise P(Add activation)      | 0.2  |
| Else add inhibition              |      |
| P(Connection disabling)          | 0.1  |
| P(Gene mutation (for each node)) | 0.8  |

### Crossover parameters

|                           |      |
|---------------------------|------|
| P(Interspecies crossover) | 0.01 |
| P(Re-enabling gene)       | 0.25 |

Table 1: Parameters used to evolve individuals

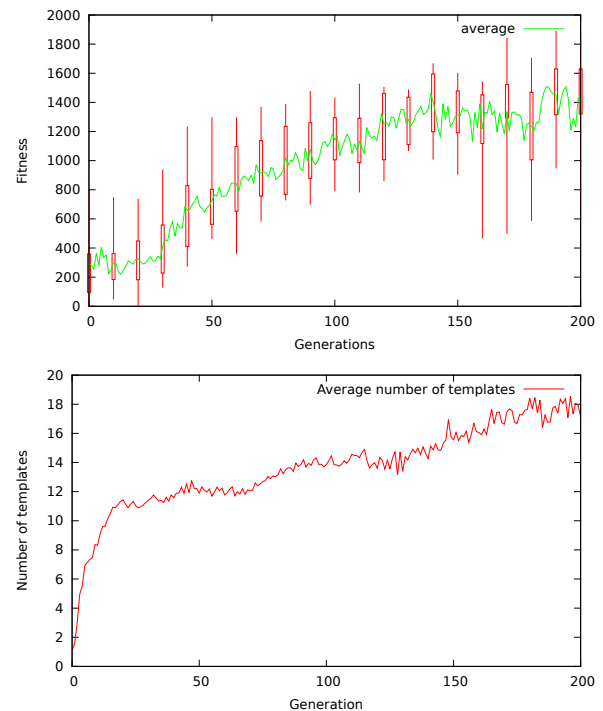

Figure 4: Top: average *a posteriori* fitness of the best individuals, as well as minimum, maximum, first and third quartiles. While noisy, the curve still shows an increasing trend similar to that of a logarithm. Bottom: the average number of templates in individuals over generations in a typical run. The trend is similar to that of the fitness, showing that bloating stays within acceptable limits.

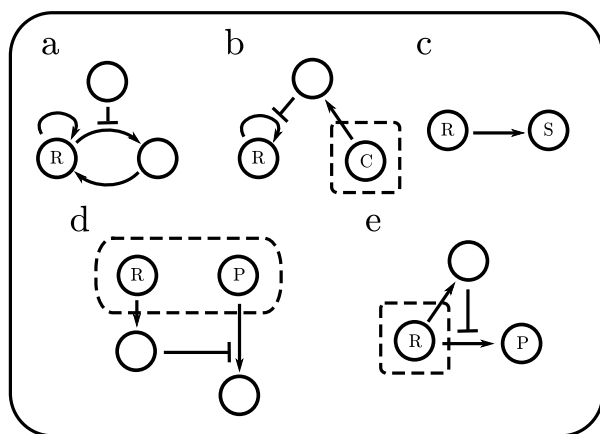

Figure 5: Basic mechanisms observed in individuals. (a.) Noise generation with two activation level. When the additional path is inhibited, the main sequence will still have a high concentration, but not high enough to be this turn's move. (b.) A given move's concentration is kept low for some time by being inhibited by the clock sequence C. (c.) A very simple feint: while pretending to play rock (the sequence R) has a non-zero concentration), the individual is actually playing scissors (S), which would win against the expected reaction of the opponent. This mechanism is often decorated with various other systems to balance the concentrations of one sequence relatively to the other. (d.) Simple comparison mechanism. The reaction path from the opponent's move will only be activated if the concentration of paper (P) is high enough, compared to the concentration of rock (R). (e.) A fold change detector, allowing the monitoring of the increase in the concentration of the rock (R) sequence of the opponent. Often, the detection will happen after a first amplification of the monitored signal.

my opponent plays rock, I will not play scissors"). Cheating leads in some cases to the apparition of oscillatory behaviors, as both individuals are both trying to play the winning move.

### Defense mechanisms

Once cheating appears, it quickly spreads among the whole population, either by cross-over, elimination of individuals which could not adapt, or by parallel discovery of the mechanism. From there on, the only way to improve is to develop mechanisms against the other cheater's spying while at the same time improving the monitoring of its current move. Many defenses were expressed among the evolved individuals, but can mainly be separated into five categories: noise generators, stealth, feint, concentration comparators and fold change detectors. Representatives of all those categories are shown in Figure 5.

Noise generators are the easiest form of defense. Since it is fair to assume that the opponent will monitor at least

two move sequences to decide its own next move, a simple yet efficient way to keep it off track is to continuously generate all sequences. This is a valid action, since only the highest sequence decides which move is played. Having a weak autocatalytic connection is enough, as long as there is a way for the other sequences to become lower (remember that an individual has to be able to play all moves to have a good fitness). Often, such sequence will have an additional catalytic loop using an additional sequence. This loop is only activated when this sequence is supposed to be played. This simple mechanism allows the individual to have multiple activation levels (by opposition to just "on" and "off"), with a better control on the final concentration of the target sequence rather than using activation mechanisms from different possibly not trustworthy part of the system.

Stealth is the complementary of noise generation. Instead of hiding one's true move among decoys, it is kept at a concentration as near to zero as possible until the last moment. This technique relies on monitoring the clock sequence, since timing is extremely important. The clock sequence is used to generate a large amount of timer, which in turn inhibits a specific move. If the inhibition is stable enough, the target sequence will be kept low until the timer has been degraded. If the delay is not long enough, the opponent will still have time to read and adapt. On the other hand, if the delay is too long, the move will not be valid. Part of the system dedicated to this mechanism seems to be very stable over generations, since it is based on a delicate balancing of parameters where any change can prove deadly.

Feint resembles closely the previous two strategies, but uses a different structure. In this case, the individual spoofs a specific move (say "rock"), but this very move also activates the generation of the real move (for instance "scissors"), often through a long activation path to generate delay. It relies on the fact that the opponent will try to adapt to the perceived move, and won't be able to react in time to the change. The system may be reset by the clock, or by a change in the opponent's perceived move.

As the direct monitoring of sequences became less and less reliable, structures to compare absolute concentrations as well as detect sudden modifications became more and more common. Concentration comparison is done through the inhibition of a reaction path if its activation is not strong enough compared to the reference. Since this inhibition originates from the monitoring of another sequence, the first pathway is activated only if the first sequence has a higher concentration. Of course, by tuning the strength of pathways and inhibition, it is possible to have more specific control over the targeted ratio between the two sequences. For instance, it would be possible to slightly modify the system to inhibit the reaction path only if the compared sequence has a concentration multiple times higher than the reference sequence. This defense mechanism is used to counter noise generators and feints.

The last technique commonly spread among individuals is a way to detect concentration increase. While concentration comparison is able to detect that a stealthy move is being played, it is only able to do so once the move became dominant (which, if the other player is timing right, should be too late). However, by using a monitoring coupled with incoherent feedforward, individuals are capable of detecting rapid variations in concentration, which would be a sign that their opponent is about to switch their move. Some individuals also *pretended* to switch their move to throw such defense technique off guard, but this was quickly countered by a mix of both direct comparison and incoherent feedforward.

## Memory vs cheating

Quite early on, individuals with a basic memory, such as the bistable from Figure 1, appear in the population. However, those individuals were too “naive” in the sense that they had no defense against cheaters. Moreover, cheating requires about the same amount of mutations to appear, or even less if partial (that is, the individual can read *some* moves, but not all). For this reason, it seems that it is much more advantageous for individuals to focus only on attack and defense. This prevented the reappearance of memory in later generation, leading to purely reactive individuals.

## The arms race

Looking at individuals over time shows the apparitions of the different cheating and defense mechanisms over time, with a noticeable complexification of the best individuals. Figure 6 shows such individuals at different times of a specific run, highlighting the apparition of various mechanisms.

The logical conclusion of this evolution strategy is that individuals with high fitness in a given generation have very little, or even no structures that are not related to cheating and defeating. Even when they exist, such structures are mutated during the next few generations to serve some attack or defense purpose. We performed an *a posteriori* evaluation of the fitness to check whether this increase in individuals size was indeed justified or only bloating. By performing this evaluation, we get a sense of the improvement of individuals over time that cannot be deduced from the lexicographic fitness used for evolution, since the later one only compares individuals from a given generation. The fitness itself is computed by making the best individual of all generations fight each other and score points in the same fashion than in the second part of the lexicographic fitness.

The trend of the *a posteriori* fitness also implies that there is no cyclic effect. While the lexicographic fitness guarantees that all individuals have the capacity of playing any move given the right conditions, there could be more advanced strategy displaying such cyclic dynamics. For instance, individuals using stealth are beaten by individuals using incoherent feedforwards, which could have been, in

Generation 10: partial cheating.

Generation 14: complete cheater.

Generation 109: stealth. The clock sequence (here designated  $A$ ) hides a move ( $b$ ).

Generation 122: fold change detector. The sequence  $c$  both activates and inhibits the creation of  $a$ . However, the activation path is longer than the inhibition path, meaning that  $a$  (rock) is only activated by this module if the concentration of  $c$  (scissors) is decreasing. Since  $c$  is directly linked to the opponent's  $b$  (paper), this individual is protected against stealthy play of  $b$ .

Figure 6: Individuals generated during a run. The color of activation nodes indicates their stability, going from red (very unstable) to blue (very stable). Green nodes are inhibitors. The notation for the moves rock, paper and scissors is respectively  $a$ ,  $b$  and  $c$ . References to the opponent's sequences are designated by a leading  $C$ .  $A$  represents the clock.

turn, beaten by another strategy that is weak against stealth. Since the fitness increase is monotonic (if we ignore the noise), we can conclude that the arms race is open-ended, with complexification of individuals the only possible way to improve.

We could also note that the arms race pushes individuals to perform well within their own ecosystem, but not always optimally. For instance, the individual from generation 122 in Figure 6 only defends against stealthy changes in the concentration of “paper”, leaving it open to the exact same strategy, if performed on another move. However, it is easy for a human designer to take inspiration from those modules to create an “optimal” player.

## Conclusion

In this work, our first hope was to observe the emergence of memory to allow non-trivial strategies at rock-paper-scissor using bioNEAT, a modified version of NEAT designed to evolve chemical reaction networks from the DNA toolbox. However, the very rules, derived from experimental settings, we set for the games prevented this mechanism from being efficient. Instead, increasingly complex cheating seemed to be the best answer. However, this is not the only thing we learned from this exercise. While having DNA systems compete against each other and evolve new (cheating) strategies can be a goal in itself, the systems evolved along the way gave us also more insight about DNA computing systems. In particular, it was possible to observe the emergence of particular structures with interesting dynamics, which may prove useful to a human trying to develop DNA systems, like with the libraries of (Rodrigo et al., 2011). It could be also interesting to make individuals compete against a human designed “optimal” cheater and see if they can evolve even more advanced strategies to counter it. Furthermore, since the DNA toolbox mimic the behavior of gene regulatory circuits (Montagne et al., 2011), an open question would be whether those mechanisms appear in real life or if they are only valid in the toolbox. Also, it would be interesting to extend the current systems to take into account reaction-diffusion and be able to play more complex games. There is little doubt that such systems will have their own share of remarkable mechanisms.

## Abstract

We construct and analyze a discrete fitness landscape called *metabolic adjustment landscape*, from sub-networks covered by different productive flux distributions of a metabolic network. The topological structure of this landscape, i.e., the local minima and saddle points, can be compactly represented as a hierarchical structure called *barrier tree*. The switching from one local optimal flux pattern to another one is accompanied by adjustment costs, since genes have to be turned on or off. This phenomenon gives rise to saddle points in the metabolic adjustment landscape. Our approach allows calculating the minimal cost pathway that connects any two local minima in the landscape. Furthermore, our method yields a detailed ordering which reactions have to be (de-)activated to switch from one flux distribution to another one with minimal adjustment costs. Such a mechanistic hypothesis can guide experimental verification. We apply our approaches to a network describing the central carbon metabolism of *E. coli*.

## Introduction

In recent years information from high-throughput sequencing and metabolomics has been integrated into genome-scale high quality reconstructions of metabolic networks of various organisms (Thiele and Palsson, 2010). These networks are a valuable computational resource in areas such as metabolic engineering, white biotechnology or synthetic biology. In particular questions how changes in the genetic setup of organisms influence the distribution of mass fluxes through a metabolic network have shifted into the focus of research. Flux balance analysis (FBA) (Orth et al., 2010) is among the most popular computational techniques to calculate such flux distributions. Since FBA is an optimization method, the organismal phenotype is usually defined in the form of a biological objective function (Feist and Palsson, 2010) which is optimized under additional constraints that balance or impose bounds on the system.

Another set of fundamental question, very appealing to theorists, focus on how catalyzed reaction networks, i.e. metabolisms, evolve and how novel reaction chemistry emerges during the evolutionary process. In Forst et al. (2006) it was shown that the structure of metabolic networks at the level of the individual chemical reactions, con-

tains enough information for the accurate reconstruction of the phylogenetic relationships. In Flamm et al. (2010) a graph grammar based computational framework for the co-evolution of the enzymes and the metabolic network was described and several scenarios of metabolic network evolution were analyzed. Complexity questions on how to find chemical motifs in chemical reaction networks were analyzed in Andersen et al. (2012). In Schuetz et al. (2012) a large data set of flux distributions measured with <sup>13</sup>C-labeling experiments was analyzed to unveil the principles that govern the distribution and change of metabolic fluxes in *E. coli* under varying conditions. A multi-objective optimization approach together with FBA was used since a combination of several competing objective functions turned out to be best suited for the analysis of the entire data set. Interestingly the study found that flux distribution in *E. coli* is governed by the principle of maximizing production only up to the degree where an easy switch of nutrients is still possible. This behavior seems to be a perfect adaption of *E. coli*'s metabolism to a fluctuating environment where a sudden deficiency of a set of nutrients can be compensated by a switch to other ones accompanied by an easy restructuring of the original flux distribution to the new situation. This comes at the cost that production of compounds (e.g. for building up biomass) in the metabolic network can never be fully maximized to the theoretical limit within the metabolic network of *E. coli*.

While there are several sophisticated computational methods to assign one "optimal" flux distribution to a metabolic network (for a review see Lewis et al. (2012)), to the best of our knowledge, this is the first study that analyzes the entire variety of (optimal) flux distributions over a metabolic network with a fixed genetic setup, but varying activity for subsets of genes in the discrete landscape metaphor.

The brief outline of this paper is as follows: we will first introduce barrier trees for discrete fitness landscapes. Then we will explain different methods how to create metabolic adjustment landscapes, which we use for barrier tree analyzes. We expect the reader to be familiar with the concept of FBA, for an in depth introduction we refer to (Palsson,

2006). In the results section we will first present an artificial example to illustrate our approaches, and then analyze two metabolic adjustment landscapes of *E. coli*.

## Barrier Trees

The switching between different productive flux distributions is accompanied by flux adjustment costs, since genes have to be regulated to achieve the change in the flux distribution. This raises saddle points which connect basins associated with optimal (productive) flux distributions. It seems therefore natural to apply the theory of discrete fitness landscapes to characterize the discrete landscape induced by flux adjustment costs and to get a deeper understanding of its topological and functional structure.

Formally, we define a landscape as a triple  $(X; N; f)$  consisting of a set of configurations  $X$ , a topological structure  $N$  that determines the mutual accessibility of configurations, and a cost or “fitness” function  $f : X \rightarrow \mathbb{R}$ . In our case elements in  $X$  will be metabolic networks. The neighborhood relation  $N$  is typically defined by the “move set”. In this contribution we will restrict ourselves to the simplest case in which the configuration space  $(X; N)$  is a finite directed graph  $G = (X; E)$  with vertex set  $X$  and edge set  $E$ . Here edges connect configurations that can be inter-converted by a single move. (If the move-set is symmetric,  $(X; N)$  can also be represented as an undirected graph.) The fitness value of the lowest saddle point separating two local minima  $x \in X$  and  $y \in X$  is

$$\hat{f}[x, y] = \min_{\mathbf{p} \in \mathbb{P}_{xy}} \max_{z \in \mathbf{p}} f(z) \quad (1)$$

where  $\mathbb{P}_{xy}$  is the set of all paths  $\mathbf{p}$  connecting  $x$  and  $y$  by a series of consecutive operations from the move set.

If the fitness function is non-degenerate, i.e., two configurations have distinct fitness values, then there is a unique saddle point  $s = s(x, y)$  connecting  $x$  and  $y$  characterized by  $f(s) = \hat{f}[x, y]$ . The extension to degenerate fitness functions is discussed in detail in Flamm et al. (2002). To each saddle point  $s$  there is a unique collection of configurations  $B(s)$  that can be reached from  $s$  by a path along which the fitness value never exceeds  $f(s)$ . In other words, the configurations in  $B(s)$  are mutually connected by paths that never go higher than  $f(s)$ . This property warrants calling  $B(s)$  the *valley or basin below the saddle*  $s$ . Furthermore, suppose that  $f(s) < f(s')$ . Then there are two possibilities: if  $s \in B(s')$  then  $B(s) \subseteq B(s')$ , i.e., the basin of  $s$  is a “sub-basin” of  $B(s')$ , or  $s \notin B(s')$  in which case  $B(s) \cap B(s') = \emptyset$ , i.e., the valleys are disjoint. This property arranges the local minima and the saddle points in a unique hierarchical structure which is conveniently represented as a tree, termed *barrier tree*.

## Landscapes of Metabolic Adjustment Networks

A metabolic (reaction) network, is usually represented as a hyper-graph, where the nodes indicate the set of chemical compounds that are connected by hyper-edges corresponding to the set of chemical reactions  $R$ . The power-set of  $R$  induces a whole series of “smaller” instances of metabolic networks, where a subset of reactions is removed from the original metabolic network. A *metabolic adjustment landscape* is a directed graph  $(X, E)$  with a vertex set (or configurations)  $X$ , where each vertex  $x$  corresponds to one of the metabolic network induced by an element of the power-set of  $R$ . The topological structure of the metabolic adjustment landscape is defined by the neighborhood function  $N$ , which determines how the “different” metabolic networks are connected via operations from the move set. In the simplest case the move set is defined by adding or removing exactly one reaction. An edge is labeled with the name of the reaction that has been added or removed (see right of Fig. 1). If the reaction is removed, there is a “-” in front of the name. Two vertices are connected by two edges going in opposite directions, if it is possible to go from one network to the other by adding/removing a reaction. The aforementioned configurations space is converted into a discrete landscape by assigning a fitness value  $f(x)$  to each configuration  $x$ . However, some of the networks are not “viable” in the sense, that these networks cannot support flux between predefined input and output nodes. The viability of a network is decided by running a FBA with a predefined objective function. If the network is viable the assigned fitness value is the number of reactions in that network and infinity otherwise. The rational behind this fitness function is, that the expression of genes, to provide the corresponding chemical transformation in the network in the form of enzymes, is a costly process. In that sense the chosen fitness function quantifies the active or expressed portion of the genetic setup i.e. all possible enzymes encoded in the genome of an organism. More formally

$$f(x) = \begin{cases} |x| & \text{if network } x \text{ is viable} \\ \infty & \text{otherwise,} \end{cases} \quad (2)$$

where  $|x|$  is the number of reactions (or hyper-edges) in a metabolic network  $x \in X$ .

## Unrestricted and Restricted Landscapes

Furthermore, we distinguish two cases of metabolic adjustment landscapes. First, the *unrestricted* case, where any active reaction can be removed and any inactive reaction may be added. In other words two networks are connected if their symmetric difference consists of exactly one reaction. Since any reaction can be removed or added networks can be generated which cannot support flux between source and sink nodes. Hence, unviable networks are valid configurations in unrestricted metabolic adjustment landscapes. Second,

the *restricted* case, where adding and removing reactions is constrained by the following rationales: (i) reactions which would cut the last connection between source and sink nodes cannot be removed (this guarantees, that every network is viable) (ii) reactions can be inserted if all their reactants are produced by “other” reactions already in the network (iii) reactions can be removed if they do not disable following reactions. A reaction is disabled if no other reaction produces its reactants.

### Fitness Functions for Networks in Metabolic Adjustment Landscapes

The standard fitness functions used for FBA are usually defined via a deviation to a given target flux, aiming at biomass production, or aiming at maximizing the production of one or more products. For a critical assessment of the assumptions made in FBA see Schuster et al. (2008). All these fitness functions do not account for the fact, that adding a reaction to a metabolic network induces costs (i.e., the genetic setup needs to be more complicated, as the corresponding enzymes need to be available). More formally this can be phrased as a Lemma.

**Lemma 1.** *Within the landscape of a metabolic adjustment network, any of the standard fitness functions for FBA (Schuetz et al., 2007) leads to a barrier tree with exactly one leaf node.*

*Proof.* A landscape of metabolic networks has a barrier tree with exactly one leaf node (i.e., a barrier tree without any barriers) iff the landscape is (possibly weakly) unimodal. To show the unimodality, consider a flux balance analysis on a metabolic network  $x$  that reaches an optimal fitness score  $f(x, v)$  with a certain optimal flux distribution  $v$  (the flux vector  $v$  assigns fluxes to all reactions). The core observation to be made is, that extending network  $x$  to a network  $x'$  can not lead to a worse fitness score, as the flux induced by  $v$  in the extended network reaches at least the fitness score  $f(x, v)$  in the network  $x'$ . Adding all possible reactions successively will therefore always lead to the best possible fitness score (without the need to cross a barrier) and two strict local minima can not exist in the metabolic adjustment landscape.  $\square$

Based on the above observation that no barriers can appear if a standard fitness functions for a FBA is used to analyze metabolic adjustment landscape, we use as a natural motivation in creating a new fitness function, that adding a reaction needs to be penalized, i.e., the genetic setup is more complicated. We therefore defined the fitness function as given in Eqn. 2. Note, that this ensures that extending a metabolic network by a reaction leads to a worse fitness score, even if the added reaction is not used in an optimal flux in the extended network (where optimal is meant wrt. to the objective function used for the FBA).

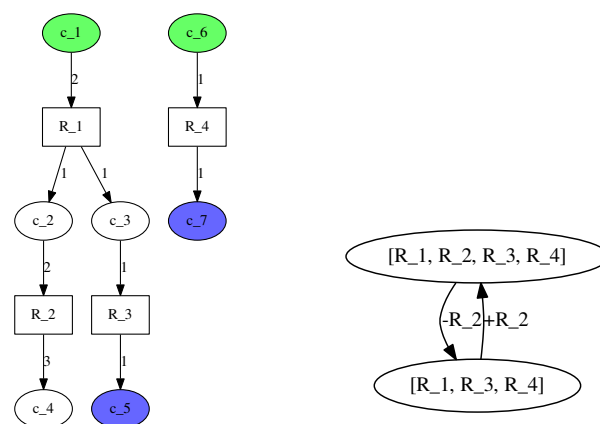

Figure 1: Toy example for a restricted metabolic adjustment landscape: The four given reactions are  $R_1, \dots, R_4$ , educts are  $c_1$  and  $c_6$  (green circles), and the target compounds are  $c_5$  and  $c_7$  (blue circles). Left: the metabolic network consisting of all reactions, the stoichiometric coefficients of the reactions are given by the weights on the hyperedges. Right: the resulting restricted metabolic adjustment landscape.

Fig. 1 shows an illustrative example with four reactions  $\mathcal{R} := \{R_1, \dots, R_4\}$ , the set of educts is  $\{c_1, c_6\}$  (sources), and the set of products is  $\{c_5, c_7\}$  (sinks). The restricted landscape has two nodes only, the fitness values of the two metabolic networks are 3 (in the network without reaction  $R_2$ ) and 4 (in the network with  $R_2$ ). The unrestricted landscape consists of  $2^{|\mathcal{R}|} = 16$  metabolic networks. The additional 14 metabolic networks are all unviable, since removal of reactions  $R_1, R_3$  or  $R_4$  disconnects the last path between the source and the sink nodes, rendering a productive flux impossible. Therefore the fitness value of these networks is set to  $\infty$ .

## Results

In the first part we will present results for an artificial example to illustrate our approach to infer a barrier tree from a metabolic adjustment landscape. In the second part we will apply our approach to the metabolic adjustment landscape derived from the main reactions in the central carbon metabolism of *E. coli*.

### Artificial Example

We used a network of 23 compounds and 25 reactions as depicted in Fig. 2. Compound  $c_{17}$  is the only substrate (source) and compound  $c_5$  is the only product (sink) compound to be produced in a quantity of 0.1. We computed the restricted metabolic adjustment landscape, which consists of 561 metabolic networks. This is relatively small in contrast to the unrestricted landscape which is comprised of  $2^{25}$  networks, the majority of these networks are unviable. The restricted landscape was analyzed: it has 5 local min-

ima, all of them reach a fitness value of 10 reactions. Note, that any local minima can not have an unused reaction in an optimal flux distribution, as this reaction could be removed (leading to a better fitness in the metabolic adjustment landscape) while keeping the same fitness for the FBA of the reduced network. The barrier tree is shown in Fig. 3, the metabolic networks that correspond to minima 1 and 2 are depicted in Fig. 2 (the red nodes and edges, are only shown for illustration purposes and are not part of the solution networks which correspond to the local minima 1 and 2, these parts are shown in green). The barrier tree calculation allows backtracking the minimum cost path between any two minima in the barrier tree. Such a minimum cost path leading from minimum 1 to minimum 2 on the restricted metabolic adjustment landscape would (i) add the reactions with indices 10, 13, and 15, (ii) remove the reactions with indices 7, 8, and 12 (this became possible since step (i) introduced a parallel path connecting the source to the sink node keeping the network viable). This minimum cost path results in a barrier of 13 (denoted as B1 in Fig. 3) between the two local minima 1 and 2 since the saddle point network contains exactly 13 active reactions. The relations between the local minima and the minimum saddle points in the metabolic adjustment landscape can compactly be represented as a barrier tree Fig. 3. The internal tree nodes are the minimum saddle points between local minima which are located at the leaf nodes. For a change to a flux pattern that uses only the pathway via reaction indices 20, 19, ..., a barrier of height 20 needs to be crossed. This barrier is denoted as B2 in Fig. 3.

### The Central Carbon Metabolism as a Restricted Landscape

The Central Carbon Metabolism (CCM) is a union of well known catabolic pathways, such as glycolysis and tricarboxylic acid cycle (TCA), and a minimal number of “interface reactions” to important anabolic pathways, found in all three kingdoms of life. The representation of the network we use originates from de Figueiredo et al. (2008). Their network has 37 reactions, provided that both directions of reversible reactions are counted separately. The target compound is glucose-6-phosphate (G6P). The network can “feed” on different substrates (source compounds) to achieve the production of G6P (target compound). Among them are Acetyl coenzyme A (AcCoA) created as degradation product of the fatty acids metabolism, the two amino acids Alanine (Ala) and Aspartic acid (Asp), or Pyruvate (Pyr), the simplest  $\alpha$ -keto-acid derived as end-product of Glycolysis. We pruned unused reactions from the original network to increase computational speed. For this an elementary mode (EM) analysis (Papin et al., 2004) of the CCM with and without Isocitrate lyase EC 4.1.3.1 (ICL) and the Malate-Aspartate shuttle (MAS) using each substrate was conducted. (An elementary mode is a certain feasible flux distribution; all elementary modes can be created by com-

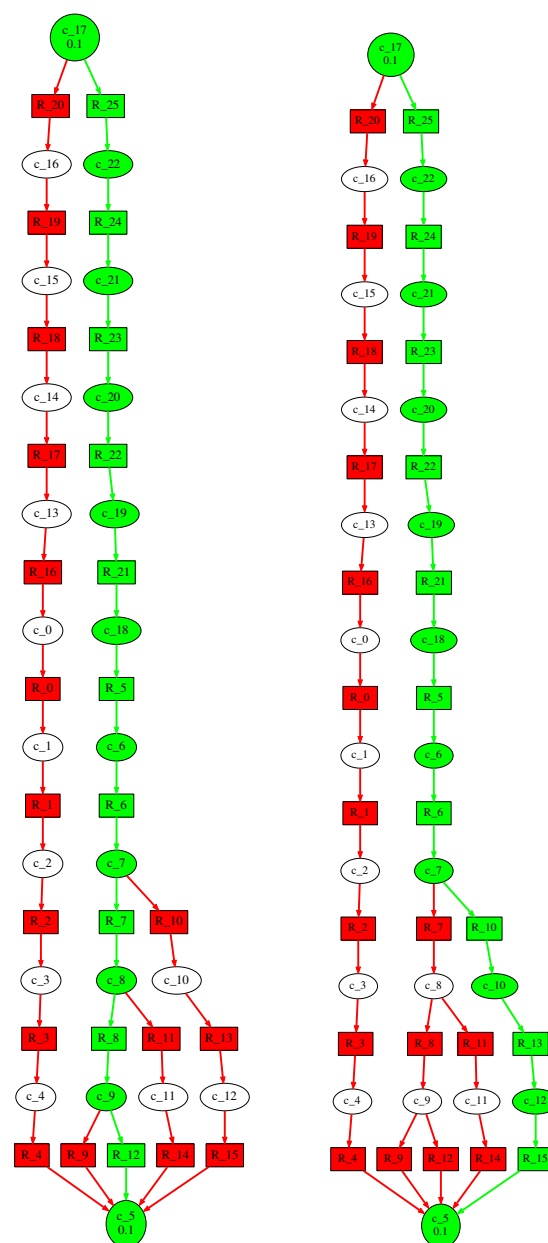

Figure 2: Minima 1 (left) and 2 (right) of the artificial example. Target is  $c_{5\_cell}$  with an outflux of 0.1;  $c_{17\_cell}$  is a substrate with an influx of 0.1; the weights on the edges indicate a steady-state flux distribution. Note that the red nodes are not in the corresponding metabolic network, but are only depicted for illustration reasons.

binning the extreme pathways (EPs) of the network, which are formally derived from the basis vectors of the null-space of the stoichiometric matrix of the network. The EPs are therefore a subset of the elementary modes.) From the set of all possible EMs it can be seen that some directions of reversible reactions are never used. We also removed the linear pathway for creation of “G6P” from Fructose-

Figure 3: Barrier tree for the metabolic adjustment landscape of the artificial example: minima 1 and 2 (both reaching objective value 10, cmp. Fig. 2) are connected via the lowest saddle B1, which has an objective value of 13. The height difference of nodes (i.e. minima and saddles) in the barrier tree corresponds to the difference wrt. their objective values. The barrier B2 has objective value 20.

1,6-bisphosphate (F1,6PP) using the 3 enzymes Fructose-bisphosphatase EC 3.1.3.11 (FBP1), Phosphofructokinase EC 2.7.1.11 (PFKL) and Glucose-6-phosphate-isomerase EC 5.3.1.9 (PGI), as any solution capable of producing "G6P" would use "F1,6PP" and this pathway. After pruning the network contains 22 reactions, having "F1,6PP" as target compound. The pruned network is depicted in Fig. 7.

**Barrier Tree** We use our approaches to determine the restricted metabolic adjustment landscape for the network given in Fig. 7. For the FBA "F1,6PP" served as target compound and AcCoA, Ala, Asp and Pyr as individual source compounds. We used the tool FASIMU (Hoppe et al., 2011) to convert the reaction networks into the integer linear programs (ILPs), which were solved using IBM's commercial program IBM ILOG CPLEX (2012) (currently freely available for academic purposes). It took 2.2 seconds to build the restricted metabolic adjustment landscape, which contains 12853 vertices. It took 36 minutes for FASIMU and CPLEX to formulate and run all 12853 simulations, i.e. on average 5.95 simulations per second. The resulting barrier tree can be seen as Fig. 4. The barrier tree has 8 local minima, the flux distributions of minima 1, 7, and 8 are depicted in Fig. 5.

**Minima** Although the biological discussion of the results is out of the scope of this paper, it should be noted that the barrier tree nicely illustrates the shift from using the glyoxylate shunt in CCM (minima 8 (cmp. Fig. 5) and 6 (not depicted)) towards not using it (all other minima).

**Barriers** The leaf nodes of the barrier tree show the CCMs different abilities to produce "F1,6PP". The barriers are

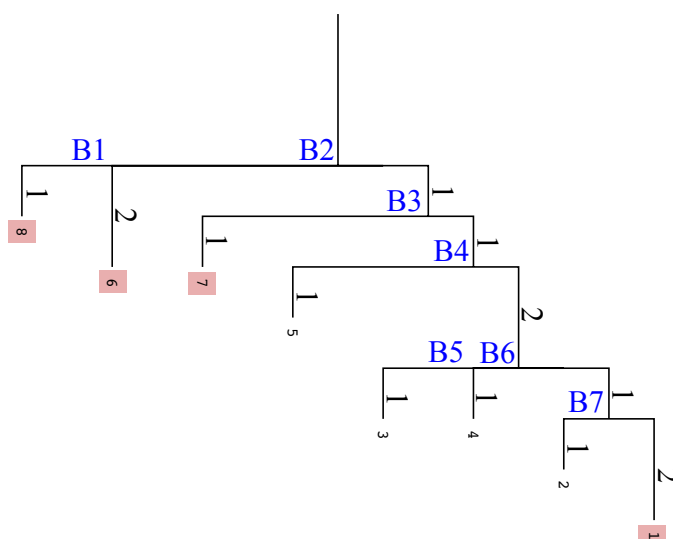

Figure 4: Barrier tree from the restricted metabolic adjustment landscape of CCM for "F1,6PP" production as objective function. Barriers are marked B1 to B7. Min 1: Use Asp. Min 2: Use Ala. Min 4: Use Asp, identical to Min 3, but with ME1\_1 and ME1\_2 blocking each other from being removed. Min 3: Use Ala. Min 5: Use Glu (utilize pathway from OG to MAL). Min 7: Use Glu (utilize pathway from OG to MAL). Min 6: Utilize AcCoA via ICL/MAS straight to OAA from Mal. Min 8: Utilize AcCoA via ICL/MAS detour over ME1\_1 and PC from Mal to OAA.

marked B1 to B7. Their fitness indicates the least amount of reactions a network needs to have when passing a barrier that is necessary to connect two metabolic networks.

Let  $M_7$  (resp.  $M_8$ ) be the network that minima 7 (resp. 8) represent. Imagine we want to modify  $M_7$  such that it becomes  $M_8$ , while always being able to maintain "F1,6PP" production and minimizing the maximal fitness of all intermediate networks. The computed minimal cost path is as follows:

|    |                                 |                  |           |

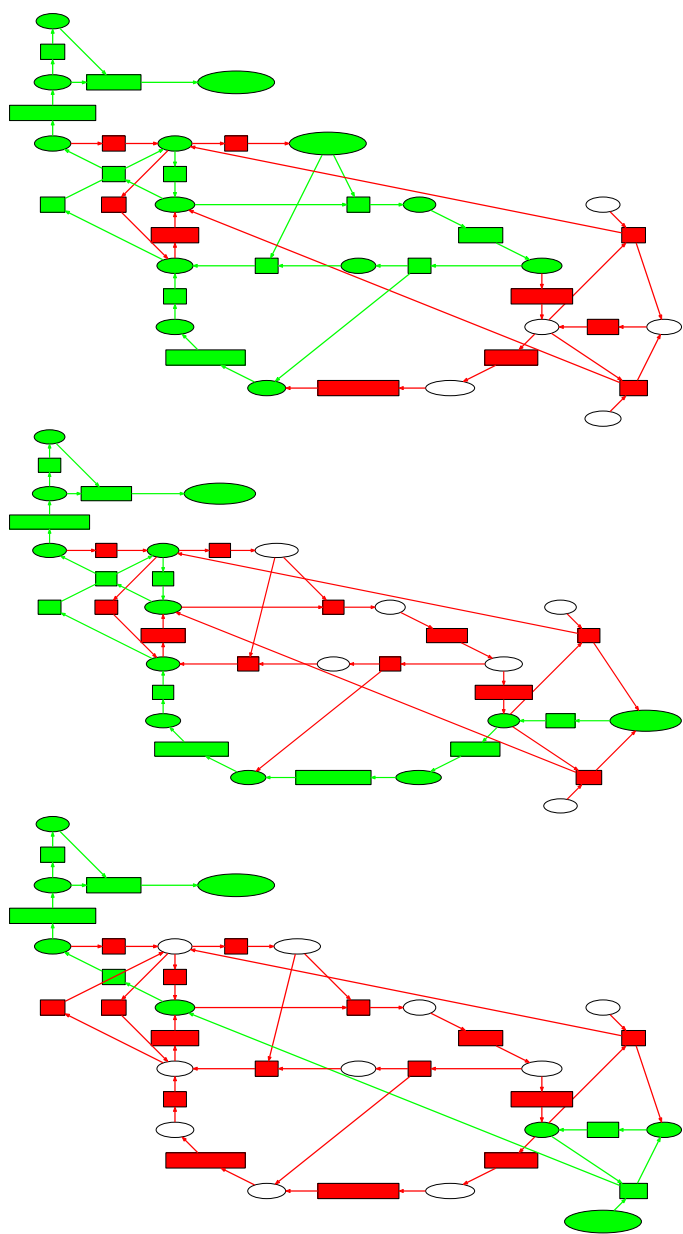

Figure 5: Minima 8 (top), 7 (middle), and 1 (bottom). Note, that the red nodes are not in the corresponding metabolic network, but are only depicted for illustration reasons.

The path never goes above 13 reactions. Although, based on the “closeness” of minima 7 and 8 in the barrier tree, one might think that connecting the two minima while not using more than 13 reactions would result in a short path, the example shows this is in general not trivial. It takes 22 steps of adding and removing a reaction. First “GPT\_1” is added to enable a shift of substrate from “Glu” to “Ala”. Using “Ala” means the 4 reactions along the path from “OG” to “OAA” are no longer needed. These are removed, as well as “ME\_1”, which is not needed either. Now “GOTH1\_1” is added to switch from using substrate “Ala” to “Asp”. This

Figure 6: Barrier B2. Note, that the red nodes are not in the corresponding metabolic network, but are only depicted for illustration reasons. The black lines depict reactions that *are* in the metabolic network but are not used in the optimal flux distribution.

removes the need for “PC” and “GPT\_1”. Now all the reactions part of the glyoxylate cycle are added, 2 of which had been removed just some steps ago. Now a shift from using “Asp” to using “AcCoA” as a substrate can be made. This transition state is barrier “B2” and is shown in Fig. 6. “GOT1\_2” and “GLUT1\_2” is now no longer needed. Last thing needed is to use “ME1\_1” and “PC” to reach “OAA” from “Mal”, instead of using “MDH1,MDH2\_1”.

### The Shift from Using Fatty Acids to Amino Acids as an Unrestricted Landscape

This section presents results that illustrate how our approach is used in order to analyze the shift between different given fluxes. Using this method instead of finding all sub-networks reduces the number of simulations, but also requires some sensible choices for the two networks. Here, we choose the networks such that both networks are subsets of the CCM and produce “F1,6PP”, but one does it using fatty acids (“AcCoA”), and the other one does it using amino acids (“Ala”, “Glu”, or “Asp”). For a biochemical discussion on the usage of fatty acids or amino acids to produce glucose see de Figueiredo et al. (2008). Both networks are shown in Fig. 7. Note, that in contrast to the restricted case, we disallow here the removal of reactions that appear in both networks (depicted as yellow hyper-edges in Fig. 7). We use the unrestricted transformation method in order to analyze the metabolic adjustment landscape. To transform the base networks topology to the target networks, 6 reactions must be removed and 6 reactions must be added. It took 0.6 seconds to build the resulting landscape, which contains  $2^{12} = 4096$  vertices. It took 10 minutes for FASIMU and CPLEX to formulate and run all 4096 simulations (i.e., on average 6,83 simulations per second).

**Barrier Tree** The barrier tree for the metabolic adjustment landscape is depicted in Fig. 8. The tree has 4 minima that

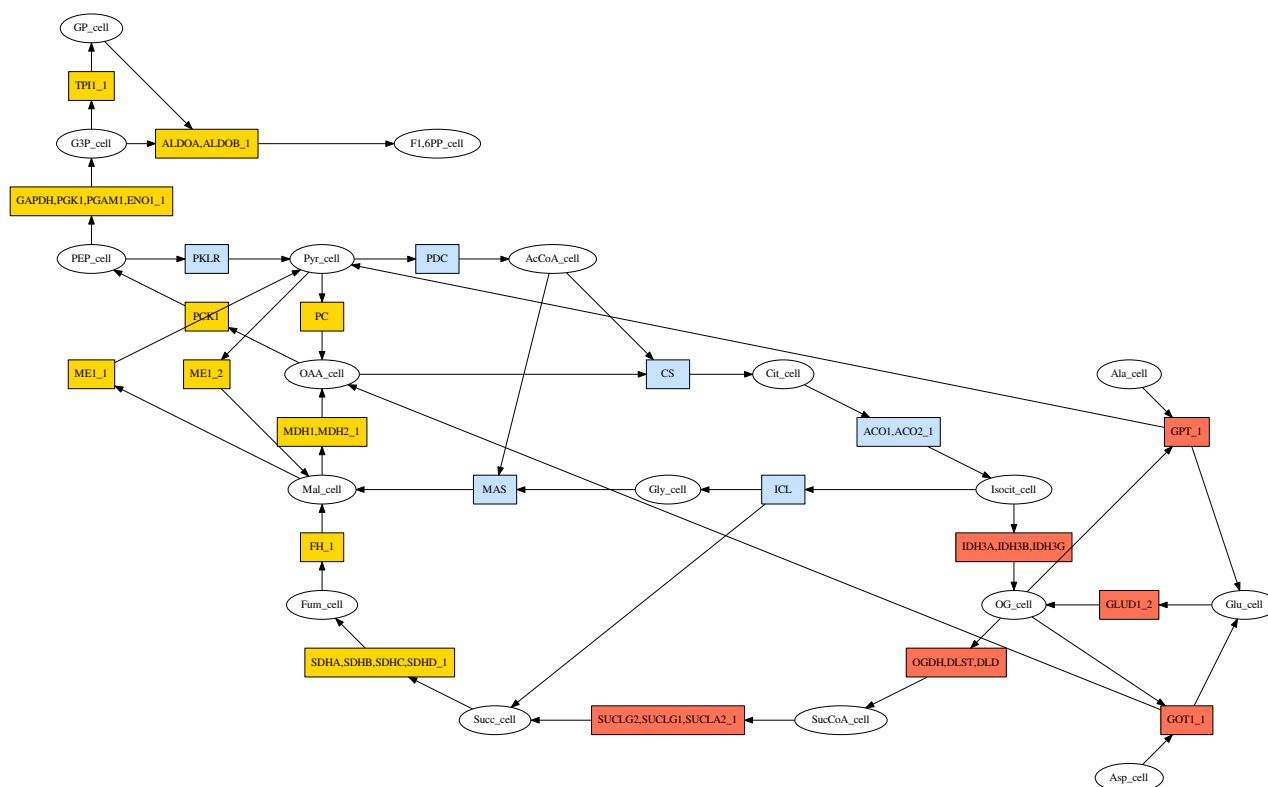

Figure 7: Two networks with an overlap that use different source compounds to analyze substrate switching: colored in yellow are reactions common to both networks, colored in blue are the additional reactions specific for the network utilizing fatty acids, and reactions colored in red are specific for the network utilizing amino acids.

Figure 8: Barrier tree illustrating the shift from utilizing amino acids (minima 1, 2, and 3) to utilizing fatty acids (minimum 4).

nicely illustrates the usage of amino acids (minima 1-3) or fatty acids (minimum 4) as source compounds to produce the target compound "F1,6PP". While changing the flux pattern between different amino acids requires passing only a small barrier of 1-2 additional reactions, switching to a flux pattern that utilizes fatty acids, in contrast, requires to pass a rather high barrier of additional 4 reactions.

**Minima** 2 of the four minima are depicted in Fig. 9. Reactions that have been removed from the network are marked

red, and the flux distribution is shown in green. Each minimum uses different substrates. Minima 1 and 2 show optimal use of both "Ala" and "Asp". They both avoid using the metabolic pathway from "OG" to "MAL", and also do not use "ME1.2". The reason for the large amount of unused "black" reactions is, that they are not allowed to be removed since they are present in the intersection of the two networks. Minima 3 uses "Glu" as source compound and requires the usage of part of the TCA cycle (from "OG" to "MAL") to connect to the target compound "F1,6PP". The barrier tree again suggests that using "AcCoA" as the only substrate requires more active enzymes than in the case of "Ala" or "Asp". In other words the amino acids are a "much cheaper" resource to produce "F1,6PP" from then "AcCoA".

## Conclusions

We introduced a systematic approach to characterize the flux landscapes of a metabolic network. The genetic setup of the metabolic networks is the always same (forming a super-network); embedded are different optimal flux distributions for varying substrate usage and/or target compound productions. Switching between different flux distributions is accompanied by adjustment costs since inactive genes have to be activated and active genes have to be deactivated.

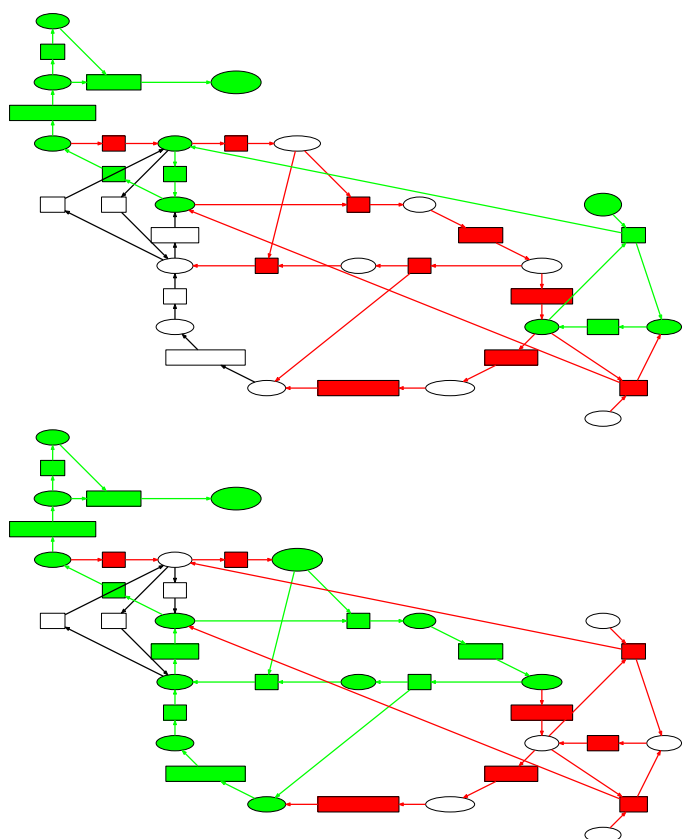

Figure 9: Minima 1 (top): Only uses substrate "Ala" in an optimal fashion by avoiding the metabolic pathway from "OG" to "MAL". Minima 4 (bottom): Only uses AcCoA as substrate and utilizes the glyoxylate shunt by activating the reactions "ICL" and "MAS". Note, that the red nodes are not in the corresponding metabolic network, but are only depicted for illustration reasons. Black edges are unused existing edges in the optimal flux distribution.

From the networks induced by the subset of active reactions (genes) a discrete landscape can be constructed, which we termed *metabolic adjustment landscape*. This landscape is analyzed in terms of local minima and connecting saddle points, and can be efficiently visualized in a hierarchical structure called *barrier tree*. The analysis allows us to find the cost for changing from one optimal flux pattern to another. Furthermore, for the first time, we can calculate in mechanistic detail how this minimal cost pathway looks like, in particular in which order the reactions have to be (de-)activated to achieve the change in the flux distribution. This mechanistic hypothesis can be tested by experimental approaches.

## Abstract

The field of synthetic biology aims to understand the mechanisms of biological systems by designing and constructing artificial biological systems from molecular parts. One of the ultimate goals of the approach is to develop an artificial cell that is under the control of scientists. Although the creation of a bacterial cell controlled by a chemically synthesized genome was accomplished in recent years (1), the construction of a self-replicable artificial cell by organizing essential purified biological macromolecules remains to be achieved (2). Such bottom-up approach is an alternative way for the construction of minimal cells to the top-down approach utilizing natural living cells, which can be helpful for us to explore the boundary between life and non-life.

Here, we reconstituted the protein synthesis system on a glass microchip. By integrating the PURE (Protein synthesis Using Recombinant Elements) system (3), a reconstituted cell-free protein synthesis system composed of purified factors and enzymes responsible for the gene expression in *Escherichia coli*, on a glass microchip, we performed the GFP synthesis with continuous flow in a microchip for the prototype verification.

Biotinylated DNA template encoding the gene for GFP was immobilized on streptavidin-coated sepharose beads with diameter of 34  $\mu\text{m}$ . Prepared beads were introduced into a Y-shaped microchannel in a glass microchip with a 10- $\mu\text{m}$  height dam structure fabricated by 2-step HF wet etching method (Fig. 1) (4). By introducing the components of the

PURE system into this microchip by syringe pump, fluorescent intensity of the recovered solution was demonstrated to be higher than the solution before introduction, indicating that the GFP was successfully synthesized on the microchip.

Because the device has an ability to comprise DNA molecule within it, which can be transcribed to RNA or translated into the protein, the results indicate that it has a potential to be a container of reconstituted life with genetic information. Furthermore, all the macromolecules of the PURE system, tRNA, ribosome, translation factors, RNA polymerase, and several enzymes, consist of RNA and proteins, which can be synthesized by the PURE system, the study sheds light on the way of reconstituting self-replication inside the device, which is crucial for the construction of artificial cells.

### Abstract

This paper describes our recent investigations on the construction of synthetic cells. By following a bottom-up synthetic biology approach, we aim at constructing minimal synthetic cells based on the encapsulation of DNA, RNA and proteins within liposomes. We will firstly comment on the physics of solute entrapment inside liposomes, giving emphasis on a remarkable self-concentration effect discovered by us (Luisi et al. 2010, Souza et al. 2011, 2012). Next we will show how it is possible to exploit this phenomenon to reveal the formation of primitive-like, metabolically active cells starting from diluted macromolecular solutions (Stano et al., submitted). In conditions where a protein-synthesis reaction does not proceed at a significant rate, lipid vesicles can entrap all required solutes allowing intraliposome protein production. The second topic deals with the formation of simple, rudimentary primitive cell communities based on giant vesicles (GVs). Oleate-containing GV's associate between each other in the presence of poly-L-arginine to form clusters that might be taken as model of primitive cell communities. Their formation, driven by simple primitive electrostatic interactions bring about a series of distinctive features (stability, enhanced permeability, solute capture, fusion) that might emphasize the role of cooperation in origin of life scenarios, flanking the usual competition issues (Carrara et al., 2012).

### Synthetic Cells

One of the goals of synthetic biology is the construction of synthetic cells. In addition to the classical synthetic biology approach, based on the manipulation of living organisms, synthetic cells can be constructed by assembling separated molecular parts like lipids, DNA, RNA, proteins in cell-like systems called semi-synthetic minimal cells (Luisi et al., 2006). Born within the community of origin of life, modern semi-synthetic minimal cell research also looks for possible biotechnological applications (but whereas self-organization, spontaneous assembly, and primitiveness are key features of synthetic cell studies in origin of life context, controlled assembly, efficiency and reproducibility are distinctive facets of biotechnology).

Here we will firstly show how a large number of macromolecules self-concentrate inside lipid vesicles (liposomes), bringing about a remarkable rate acceleration of a complex biochemical reaction. Then, we will present our first attempt to build protocellular communities based on the physical association of giant vesicles (GVs).

### Solute entrapment and “super-concentration”

Semi-synthetic minimal cells are defined as those cell-like particles containing the minimal and sufficient number of biological compounds (nucleic acids, protein, lipids) that would allow self-maintenance, self-reproduction, and the possibility to evolve (Luisi et al., 2006). Protein synthesis is a key module of semi-synthetic minimal cell, representing not only a necessary function of the synthetic cell, but also a good model for metabolic complexity. Following our initial observation of protein synthesis in “small” conventional liposomes (200 nm diameter) (Souza et al., 2009) we started a systematic electronmicroscopy study that revealed how macromolecules like ferritin (Luisi et al., 2010), ribosomes (Souza et al., 2011) and ribo-peptidic complexes (Souza et al., 2012) were spontaneously encapsulated within liposomes (Figure 1).

**Figure 1.** (A) Poisson curve versus power-law. (B) ferritin-containing and empty liposomes. Reproduced from Luisi et al. (2010) with permission from Wiley.

Intriguingly, it was found that the intra-liposome solute distribution function does not follow – as expected – the Poisson law, but it is rather shaped as a power law (Figure 1a). In particular, although the vast majority of liposomes encapsulate a limited number of solutes, a very small fraction of liposomes (typically around 0.1%) contains instead a very high number of solutes, so that their internal concentration can

be also one order of magnitude higher than the concentration of the solutes in the environment (Figure 1b). In other words, during liposome formation, solutes can self-concentrate within the liposome cavity. We reasoned that the “super-concentration” effect could drive the formation of functional cells, for instance “protein-producing” ones, even if the low concentration of the solutes in the environment does not allow it. By diluting the transcription-translation kit at a level where no protein synthesis takes place, we simulated a primitive scenario where solutes were already present in diluted form in a sea or fresh-water lagoon. We then formed liposomes followed the course of protein production (the green fluorescent protein was used) inside and outside liposomes. Surprisingly, we found that some vesicles were able to synthesize the protein despite the low solute concentration, revealing that even a complex metabolic pathway spontaneously self-concentrates inside liposomes (Stano et al., submitted). These results provide a physical explanation to the origin of early functional cells, thanks to a favorable micro-environment created by liposomes, which can concentrate solutes inside their aqueous cavity.

### Vesicles assemblies

Current research on the origin of life typically focuses on the self-organization of molecular components in individual cell-like compartments, whereas no attempts have been made to investigate communities of compartments. Here we present our study on vesicles assemblies as a model of primitive cell communities.

At this aim, we firstly prepared giant vesicles (GVs) composed by a primitive lipid, namely oleic acid, which is negatively charged. GV membranes have been made stable by the addition of a neutral stabilizing phospholipid (POPC, 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphatidylcholine). Oleate/POPC GV were prepared after the optimization of the “droplet transfer” method, which allows the facile entrapment of solutes like enzymes and DNA.

The addition of poly-L-arginine (PLA), a positively charged polypeptide, brings about the association of negatively charged oleate/POPC GV in form of small clusters first, that in turn grow to give rise to very large clusters. The formation of these GV “colonies” is stochastic but depends on the GV numerical density as well as on the PLA/GV ratio. Typically, these clusters contain up to 100 GV. GV are also destroyed after the addition of PLA (due to high local PLA concentration), and the maximal GV to clusters conversion is about 50%.

Once formed, we characterize the GV clusters properties. Phosphate bearing water-soluble solutes, such as ADP, fluorescent diphosphate and even t-RNA, present in the environment, readily penetrate into clusterized GV much faster than isolated GV. This is probably due to the help of PLA adsorbed between GV, which acts here like the well-known “cell penetrating peptides”. GV in the cluster can fuse with each other (fusion yield ca. 0.5-1%). Fusion was revealed by preparing clusters from two GV population, each containing a fluorescently labeled macromolecule. It is remarkable that vesicle fusion might provide a mechanism for

increasing the internal molecular complexity thanks to the acquisition of new molecules originally entrapped in another vesicle. Finally, GV clusters can capture new GV from the solution and grow. The new GV attach to the cluster border, demonstrating that PLA is still present in the outer GV cluster surface.

GV clusters are firmly attached to the solid support (an hydrophobic plastic polymer, in this case, and resist to hydraulic flow.

In summary, GV clusters display several interesting features, mimicking in very simple way bacterial colonies at the lowest possible complexity level. Intriguingly, bacterial L-forms (bacteria without cell walls) and GV display some common physico-mechanical behavior.

**Figure 2.** Sagittal ( $xz$ ) ( $130 \times 30 \mu\text{m}$ ) and horizontal ( $xy$ ) ( $130 \times 60 \mu\text{m}$ ) confocal images of GV associated to form “colonies”. The GV membranes have been stained by octadecyl rhodamine. Note the flattening of GV on the plastic surface. Reproduced from Carrara et al. (2012) with permission from Wiley.

## Abstract

An intermediate step between simple models of protocells having no membrane structure and the current, complex membrane organization of modern cells considers simple forms of membrane change that interact with the protocell dynamics in predictable ways. Here we analyse a kinetic model of a simple protocell system: a bioreactor vesicle involving mechanosensitive channels. This is a closed lipid bilayer which hosts a minimal metabolism  $X + E \rightarrow W + E$  inside its internal (variable volume) water pool, and with channels anchored in the membrane. The reactor can swell, opening the channels, which in turn allow enhanced passive diffusion of solutes  $X$  and  $W$  into and out of the reactor. We calculate under what external conditions and parameter regimes the reactor is able to maintain a far from equilibrium steady state, and what behaviours are possible in this reduced complexity scenario. This study is just a preliminary step in modelling the bigger question of how osmotic force sensing devices in early membranes could couple with early metabolisms, enhancing the stability of protocells in changing environments.

## Introduction

The study of protocellular structures, both from theoretical and experimental approximations, offers a unique opportunity to approach some of the key questions associated to the emergence of life in our biosphere (Deamer, 2011). Moreover, it also provides useful insight into different ways of approaching the problem of building synthetic compartments capable of reacting to external signals while carrying internal molecular structures (Solé et al., 2007). The potential repertoire of protocellular constructs is highly constrained by the type of membrane complexity that can be used. Membranes are the interface between the internal reactions and the external, usually fluctuating world. Part of the relevant phenomena that would take place depends on the ways membranes respond to environmental signals. Early models of protocells consider some sort of passive or active diffusion process with no or little complexity. However, it would be desirable to include within the protocell framework minimal models of membrane organization reacting to environmental cues in physically realistic ways. In this paper, we consider such a property by including mechanosensitive (MS) channels as a component of our model protocells.

MS channels, found in most free-living Bacteria and Archaea, are small functional protein nano-machineries which embed in lipid bilayers and open a water-filled pore in response to tension in the membrane (Kung, 2005; Sacklin, 1995; Kung et al., 2010). Modern day bacteria such as *Escherichia coli* are known to regulate their internal state with respect to a changing osmolarity environment by using various metabolic and transcriptional means, and the MS channels in their membranes are often cited as playing an “emergency release valve” role, quickly jettisoning solutes to avoid osmolysis when the environment rapidly dilutes (Booth and Blount, 2012). However, MS channels are thought to have evolved at a very early stage in the development of bacteria (Kloda and Martinac, 2002), and it is interesting to speculate what role osmotic force sensing devices in the membranes of protocells would have played in regulating their much simpler metabolisms in changing environments (Morris, 2002).

To make a departure point in this direction, this study analyses a minimal scenario where a vesicle acting as a miniaturised reactor – metabolising substrate  $X$  absorbed from the environment, into waste  $W$ , which is later expelled – can extend its viability over a wider range of external substrate concentrations, by incorporation of MS channels into the membrane. Although near-molecular detail dynamics models of MS channels in bilayers indeed exist (Louhivuoria et al., 2010, for example), our model is placed at the coarse grain level of chemical kinetics. This allows us to accommodate time scales of seconds as opposed to microseconds, and gives a coupled membrane-metabolism system amenable to some mathematical analysis. An overview of our modelling approach, where vesicles are modelled as a series of coupled reaction domains, has recently been given by Mavelli and Ruiz-Mirazo (2010).

## Bioreactor Kinetic Model

The bioreactor model (Figure 1) consists of a lipid vesicle floating in a reservoir. The reservoir is assumed so large that solute concentrations exterior to the vesicle are approximately constant. The internal aqueous pool of the vesicle

is modelled as a well-stirred chemical domain, and a semi-permeable lipid bilayer  $\lambda$  dm thick separates this domain from the reservoir. The surface areas ( $S_\mu$ ) of the water-facing sides of the inner and outer bilayer leaflets are assumed to be equal ( $\lambda \ll$  vesicle radius). The reservoir provides an inexhaustible source of substrate  $X$  at concentration  $[X]_{\text{out}}$  molar.

When the vesicle has no MS channels in the membrane, or when the channels are not yet open (Figure 1a),  $X$  diffuses passively (with diffusion constant  $D_X$ ) into the vesicle following Fick's Law. Physical space does not have a fully fledged representation in our model, and so this diffusion is taken to happen *only across* the bilayer region separating the domains. The vesicle membrane is assumed to be made of oleic acid and in what follows, the permeabilities of solutes  $X$  and  $W$  are set to be comparable to the permeability that oleate vesicles exhibit to ribose (Sacerdote and Szostak, 2005), which defines a realistic time scale in seconds.

Once inside the internal aqueous pool of the vesicle,  $X$  is enzymatically transformed (e.g. isomerized) into product  $W$  at rate  $k$ . To keep complexity to the minimum possible, the responsible enzyme  $E$  is not explicitly modelled, but is considered trapped inside the vesicle pool facilitating the  $X \rightarrow W$  reaction, which by contrast does not take place in the external reservoir. The reverse rate of the reaction is considered negligible and disregarded.

After  $W$  is produced, it passively diffuses out of the vesicle, but with a different diffusion constant  $D_W$ . The environment is a sink for  $W$  and so at all times  $[W]_{\text{out}} = 0$ . Together with the above assumptions, this guarantees that the mass flow through the reactor is always in one direction (left to right, Figure 1) or zero.

The bioreactor model is thus a two variable dynamical system characterised by the number of  $X$  and  $W$  species inside the vesicle aqueous pool. With some terms to be explained shortly, the state vector evolves from initial condition  $\langle X_{\text{in}}^0, W_{\text{in}}^0 \rangle$  according to the following coupled ODEs:

$$\frac{dX_{\text{in}}}{dt} = (D_X S_\mu + \sigma(T_\mu) D_c N_c) \frac{[X]_{\text{out}} - [X]_{\text{in}}}{\lambda} - k X_{\text{in}} \quad (1)$$

$$\frac{dW_{\text{in}}}{dt} = k X_{\text{in}} - (D_W S_\mu + \sigma(T_\mu) D_c N_c) \frac{[W]_{\text{in}}}{\lambda} \quad (2)$$

where  $[X]_{\text{in}}$  and  $[W]_{\text{in}}$  are the molar concentrations of  $X$  and  $W$  in the vesicle pool respectively, written as  $[X]_{\text{in}} = X_{\text{in}}/\mathcal{V}$  and  $[W]_{\text{in}} = W_{\text{in}}/\mathcal{V}$ . Here term  $\mathcal{V} = N_A V$  is called the *normalised volume* of the vesicle aqueous pool, and is used in the analysis section in preference to the actual litre volume  $V$ .

It is important to note that the volume of the vesicle aqueous pool is *not constant*, but changes in time as water moves across the vesicle membrane through osmosis. Owing to its

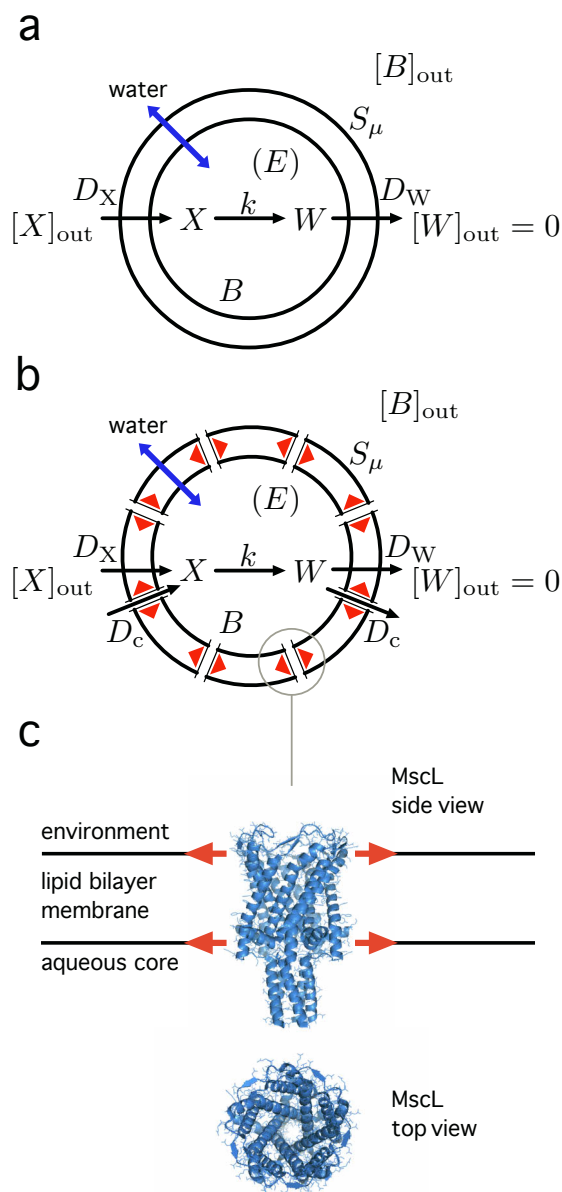

Figure 1: Bioreactor schematic. (a) A vesicle with no MS channels, or with MS channels but insufficient membrane tension to open them and (b) an osmotically stressed vesicle with MS channels open, permitting enhanced passive transport rates for solutes  $X$  and  $W$  into/out of the vesicle (red arrows denote membrane tension). (c) Molecular structure of a contemporary MS channel of type MscL (mechanosensitive channel of large unitary conductance), typically found in *E. coli* membranes, pictured here in closed conformation.

very high permeability, water is assumed to flow across the membrane instantaneously and the vesicle volume is set at every moment such that the total concentration of molecular species inside the vesicle is equal to the total concentration

outside:

$$[B]_{\text{in}} + [X]_{\text{in}} + [W]_{\text{in}} = [B]_{\text{out}} + [X]_{\text{out}} \quad (3)$$

which gives the normalised volume of the vesicle at each instant as:

$$\mathcal{V} = \frac{B_{\text{in}} + X_{\text{in}} + W_{\text{in}}}{[B]_{\text{out}} + [X]_{\text{out}}} \quad (4)$$

A fixed number of buffer molecules  $B$  are trapped inside the vesicle aqueous pool for stability purposes. These are non-reactive molecules which cannot permeate the lipid bilayer, and likewise they exist in the environment at constant concentration  $[B]_{\text{out}}$ . In this work, we choose to set the number of  $B$  in the internal aqueous pool such that the vesicle is perfectly spherical when the outside substrate concentration  $[X]_{\text{out}} = 0$  and there are no solutes  $X$  or  $W$  inside the reactor. That is,  $B_{\text{in}}$  is set such that the initial volume  $\mathcal{V}_0 = B_{\text{in}}/[B]_{\text{out}}$  gives  $\Phi = 1$  (see below).

The extent to which the vesicle is swelled, or deflated, is captured by a non-dimensional measure called the *reduced surface*:

$$\Phi = \frac{S_{\mu}}{\sqrt[3]{36\pi(\mathcal{V}/N_A)^2}} \quad (5)$$

defined as the ratio of the actual surface area of the vesicle, to the surface area corresponding to the volume of the internal aqueous pool when that volume is considered spherical in shape. When  $\Phi > 1$  the system is deflated with an undefined shape and has surplus surface area for the volume. When  $\Phi = 1$ , the vesicle is perfectly spherical, and when  $\Phi < 1$ , the vesicle is spherical but in a state of membrane tension because insufficient surface exists to perfectly wrap the volume. The reduced surface allows us to define the percentage membrane tension  $0 \leq T_{\mu} \leq 1$  as follows:

$$T_{\mu} = \begin{cases} \frac{1-\Phi}{\epsilon}, & \text{if } 1 - \epsilon \leq \Phi \leq 1 \\ 0, & \text{otherwise} \end{cases} \quad (6)$$

where the lipid membrane ruptures from excess osmotic pressure and the vesicle no longer exists if  $\Phi < 1 - \epsilon$ . This non-dimensional parameter  $\epsilon$  (the burst tolerance) therefore establishes the stability boundary of the system.

When sufficient, the membrane tension  $T_{\mu}$  activates any existing MS channels in the membrane (Figure 1b), enhancing the passive diffusion rates of  $X$  and  $W$  through the membrane. Unlike normal passive diffusion through the bilayer, where diffusion rate is influenced by specific molecular properties of solutes, the channels open water-filled pores and so are assumed to augment the passive diffusion rates of  $X$  and  $W$  equally. The  $N_c$  membrane channels are each modelled to open continuously at a percentage which is a linear function of membrane tension:

$$\sigma(T_{\mu}) = \begin{cases} 0, & \text{if } T_{\mu} \leq T_0 \\ 1, & \text{if } T_{\mu} \geq T_m \\ \frac{T_{\mu}-T_0}{T_m-T_0} & \text{otherwise} \end{cases} \quad (7)$$

for  $T_0 < T_m$ , where  $T_0$  and  $T_m$  are the percentages of membrane tension when the channels begin to open, and are maximally open, respectively. If  $T_m$  is only marginally larger than  $T_0$ , then the channels will snap open more or less instantaneously as  $T_0$  is reached. When tension in the membrane exceeds  $T_m$ , the channels are maximally extended and do not open further with increasing tension. In reality, MS channels don't open linearly, but rather open in a quantum manner through a series of mid-states. Furthermore, channels can 'flicker' back to these mid-states once opened (Sukharev et al., 2001). Considering these facts, our measure  $\sigma(T_{\mu})$  can be interpreted as the average percent conductivity per channel in the membrane at tension  $T_{\mu}$ .

When the  $N_c$  channels are fully open, the membrane diffusion constant for a solute, for example  $X$ , increases by  $1 + (D_c N_c / D_X S_{\mu})$  fold, where  $D_c$  is the effective diffusion constant for a single open channel.

Importantly, the MS channels are assumed not to permit the passage of buffer  $B$  or enzyme  $E$  into/out of the vesicle compartment. Finally, lipid flux to and from the lipid bilayer membrane is not explicitly modelled, but it is assumed that the bilayer exists in a solution where the outside lipid concentration is close to the CVC for oleic acid and thus the inside/outside vesicle surface area remains approximately stable over time at  $S_{\mu}$ . Thus, there is no possibility for membrane growth in this simplified model; the surface area is assumed not to increase under osmotic tension conditions. The parameters used in the model can be found in Table 1 below and in the figure captions.

| Parameter           | Value                       | Unit                                         |
|---------------------|-----------------------------|----------------------------------------------|
| $S_{\mu}$           | $3.1416 \times 10^{-12}$    | $\text{dm}^2$                                |
| $\lambda$           | $4.0 \times 10^{-8}$        | $\text{dm}$                                  |
| $\epsilon$          | 0.5                         |                                              |
| $D_{\text{ribose}}$ | $2.65 \times 10^8$          | $\text{dm}^2 \text{s}^{-1} \text{mole}^{-1}$ |
| $D_c$               | $D_{\text{ribose}} S_{\mu}$ | $\text{dm}^4 \text{s}^{-1} \text{mole}^{-1}$ |
| $N_c$               | 3                           |                                              |
| $k$                 | 0.009                       | $\text{s}^{-1}$                              |
| $[B]_{\text{out}}$  | 0.2                         | $\text{mole dm}^{-3}$                        |
| $B_{\text{in}}$     | 63064                       |                                              |

Table 1: Model parameters.  $S_{\mu}$  is set to the external surface area of a 50nm radius sphere, the typical surface area of an extruded unilamellar oleic acid vesicle.  $D_{\text{ribose}}$  is from (Mavelli and Ruiz-Mirazo, 2010), derived from experimental data in (Sacerdote and Szostak, 2005). Constants  $D_c$  and  $N_c$  are set such that when all MS channels are open, the membrane permeability to ribose increases 4-fold.

## Steady State Analysis

It is instructive to analyse the steady state system behaviour in two parts. The first part applies when the vesicle has *constant membrane permeability* with respect to membrane tension, namely (a) when the reactor has no MS channels, (b) when the reactor has channels but insufficient membrane tension to open them (in both cases,  $\sigma(T_\mu) = 0$ ) and also (c) when the bioreactor has maximally open channels that are no longer responsive to changes in membrane tension ( $\sigma(T_\mu) = 1$ ). The second part completes the picture by finding the steady states when the MS channels are partially open ( $0 < \sigma(T_\mu) < 1$ ) and membrane permeability depends on membrane tension.

### Reactor with constant membrane permeability

The bioreactor is defined as being in steady state when (i) the number  $X$  and  $W$  species inside are not changing (metabolic steady state), whilst at the same time (ii) osmotic equilibrium (3) exists.

Given a fixed outside substrate concentration  $[X]_{\text{out}} \geq 0$ , our objective will be to solve the model for the steady state vesicle volume  $\mathcal{V}^*$  which ensures both (i) and (ii). Normalised volume  $\mathcal{V} = N_A V$  is useful to use, since it both represents the vesicle litre volume  $V$  and provides a convenient way to convert internal species numbers to molar concentrations (by dividing by  $\mathcal{V}$ ) and vice versa. Once  $\mathcal{V}^*$  is known, all other properties of the system at steady state can be derived.

Dealing with condition (i) first, for a bioreactor where  $\sigma(T_\mu) = 0$  (no channels, or insufficient tension to open existing channels), setting (1) and (2) to 0 yields the steady state concentrations of  $X$  and  $W$  inside the vesicle, given that the vesicle volume is  $\mathcal{V}$  (a value which we are free to choose arbitrarily at this stage):

$$[X]_{\text{in}}^* = \frac{[X]_{\text{out}}}{1 + \mathcal{V}\alpha} \quad (8)$$

$$[W]_{\text{in}}^* = \frac{\beta\mathcal{V}[X]_{\text{out}}}{1 + \mathcal{V}\alpha} \quad (9)$$

where constants  $\alpha = \frac{k\lambda}{D_X S_\mu}$  and  $\beta = \frac{k\lambda}{D_W S_\mu}$ . When these internal concentrations are present,  $X$  is entering the vesicle at the same rate that it is being transformed to  $W$ , which in turn is equal to the rate that  $W$  is leaving the vesicle. For a bioreactor where  $\sigma(T_\mu) = 1$  (maximally open channels), the solutions are the same, but with constant  $\alpha$  replaced by constant  $\gamma = \frac{k\lambda}{D_X S_\mu + D_c N_c}$ , constant  $\beta$  replaced by  $\eta = \frac{k\lambda}{D_W S_\mu + D_c N_c}$ , and the requirement that volume  $\mathcal{V}$  is large enough to make a membrane tension  $T_\mu \geq T_m$ , i.e. sufficient to fully open the channels.

Now, we further constrain  $\mathcal{V}$  so that the osmotic equilibrium requirement (ii) is additionally satisfied. Substituting (8) and (9) into (3) gives:

$$\frac{B_{\text{in}}}{\mathcal{V}} + \frac{[X]_{\text{out}}}{1 + \mathcal{V}\alpha} + \frac{\beta\mathcal{V}[X]_{\text{out}}}{1 + \mathcal{V}\alpha} = [B]_{\text{out}} + [X]_{\text{out}} \quad (10)$$

which when re-arranged leads to a quadratic equation in  $\mathcal{V}$ , the solution to which yields  $\mathcal{V}^*$ , given that the outside concentration is  $[X]_{\text{out}}$ :

$$\mathcal{V}^* = \frac{(\alpha B_{\text{in}} - [B]_{\text{out}}) \pm \sqrt{\Delta}}{2a} \quad (11)$$

where coefficient

$$a = \alpha[B]_{\text{out}} + (\alpha - \beta)[X]_{\text{out}} \quad (12)$$

and the discriminant

$$\Delta = ([B]_{\text{out}} - \alpha B_{\text{in}})^2 + 4B_{\text{in}}\alpha[B]_{\text{out}} + 4B_{\text{in}}(\alpha - \beta)[X]_{\text{out}} \quad (13)$$

which becomes negative when

$$([B]_{\text{out}} - \alpha B_{\text{in}})^2 + 4B_{\text{in}}\alpha[B]_{\text{out}} < 4B_{\text{in}}(\beta - \alpha)[X]_{\text{out}} \quad (14)$$

Substituting  $\mathcal{V}^*$  into (8) and (9) reconstitutes the full state vector of the system at steady state, and substituting it into (5) gives the corresponding  $\Phi^*$ , used in the figures.

The steady state behaviour of the bioreactor is dependent on the magnitude of the diffusion constants  $D_X$  and  $D_W$  with respect to each other (Figure 2). When  $X$  and  $W$  passively diffuse at equal rates ( $D_X = D_W$ ) the reactor will always be perfectly spherical at steady state, independent of the outside substrate concentration  $[X]_{\text{out}}$ . This is because when  $\alpha = \beta$  then (12) becomes independent of  $[X]_{\text{out}}$  and (11) reduces to  $\mathcal{V}^* = B_{\text{in}}/[B]_{\text{out}} = \mathcal{V}_0$  for the parameters used. In this state  $\Phi = 1$ , thus there is no membrane tension to activate MS channels.

Conversely, when  $D_W > D_X$ , the reactor actually shrinks in volume as  $[X]_{\text{out}}$  is increased (Figure 2, inset). Thus, whenever waste  $W$  is more permeable than substrate  $X$ , the membrane will never have tension at steady state.

The most interesting case is when  $D_X > D_W$ . Here, increasing  $[X]_{\text{out}}$  swells the volume of the bioreactor, causing tension in the membrane. Figure 2 (solid black line) shows that the bioreactor follows a succession of steady states at decreasing  $\Phi$  values (increasing membrane tension) as  $[X]_{\text{out}}$  is increased. For the parameter values used, a catastrophic value of  $[X]_{\text{out}} = [X]_{\text{out}}^c$  also exists (vertical red line), passed which the system has no viable steady states, and will burst. This point corresponds to the discriminant (13) becoming negative and complex roots for  $\mathcal{V}^*$ . This cannot happen in the  $D_W > D_X$  regime, because when  $\beta < \alpha$ , equality (14) can never be true (the left hand side is always positive).

Figure 2: Steady state  $\Phi^*$  for a bioreactor vesicle with no channels, as  $[X]_{\text{out}}$  increases. Main figure:  $D_X = 2.0 \times D_{\text{ribose}} > D_W = 0.1 \times D_{\text{ribose}}$ . In region A, the bioreactor has one stable node, in regions B and C it has an additional unstable saddle point (but in region B, this point is outside the viability zone) and in region D the reactor has no steady state. Inset: steady state behaviour when magnitudes of diffusion constants reversed ( $D_X < D_W$ ) involves the reactor shrinking rather than swelling. Parameters given in Table 1. Blue circles validate the analysis by showing mean equilibrated values of  $\Phi$  from stochastic simulations of the model with the Gillespie algorithm (subsequently performed as validation in all plots).

Thus, when  $D_X > D_W$  the system also has the possibility for an *intrinsic limit* to the maximum outside substrate concentration, at which steady state is possible. This means that if  $[X]_{\text{out}}$  is gradually increased from 0, the transition from zero membrane tension to maximum membrane tension and burst (when  $\Phi < 1 - \epsilon$ ) is not necessarily smooth: the reactor can become prematurely unstable if  $[X]_{\text{out}}^C$  is encountered along the way (illustrated by the red dot in Figure 2) before reaching the viability threshold, determined by  $\epsilon = 0.5$ .

For an arbitrary set of reactor parameters  $\{D_X, k, D_W\}$ , the normalised reactor volume for which a catastrophic burst can be achieved,  $\mathcal{V}_{\text{min}}^C$ , can be shown to have a lower limit. It is derived by setting the discriminant to 0 in (11), which makes  $\mathcal{V}^* = \mathcal{V}^C$ , and then taking the limit of the resulting expression as  $\alpha$  tends to zero, which corresponds to diffusion constant  $D_X$  tending to infinity, or reaction rate  $k$  tending to 0:

$$\mathcal{V}_{\text{min}}^C = \lim_{\alpha \rightarrow 0} \mathcal{V}^C = \frac{2B_{\text{in}}}{[B]_{\text{out}}} \quad (15)$$

which can be written  $\mathcal{V}_{\text{min}}^C = 2\mathcal{V}_0$  for our choice of pa-

rameters, corresponding to  $\Phi = 0.63$ . We can guarantee that catastrophic burst cannot happen for membrane tensions less than this.

Another interesting occurrence when  $D_X > D_W$  is the appearance of an unstable saddle point<sup>1</sup> (Figure 2, dotted line). This is not always present, but happens when (12) changes sign with increasing  $[X]_{\text{out}}$ , to become negative after an initially positive value at  $[X]_{\text{out}} = 0$ . Re-arranging (12), we see that an additional unstable saddle point accompanying the existing stable node appears when:

$$[X]_{\text{out}} > \frac{\alpha}{\beta - \alpha} [B]_{\text{out}} \quad (16)$$

This point is marked on the figures as  $[X]_{\text{out}}^S$  (vertical blue lines), for the set of parameter values used. The presence of an unstable point means that not all initial conditions  $\langle X_{\text{in}}^0, W_{\text{in}}^0 \rangle$  will lead to the stable node of the system. For membrane burst tolerance  $\epsilon = 0.5$ , the unstable saddle point only becomes reachable at higher values of  $[X]_{\text{out}}$  (green vertical lines on figures).

### Reactor with MS channels

The full bioreactor model with MS channels in the membrane is actually a hybrid dynamical system. When the channels are closed, or maximally open, the system behaves as a reactor with constant membrane permeability as discussed above. In the tension region  $T_0 < T_\mu < T_m$  where the channels are opening in response to membrane tension (and thus membrane permeability is *dependent* on membrane tension), the evolution equations of the system change in the sense that function  $\sigma(T_\mu)$  is now not constant. This makes the calculation of metabolic steady state (i) in this region more cumbersome:

$$[X]_{\text{in}}^* = \frac{[X]_{\text{out}}(k_1 - k_3\mathcal{V})}{(k_4 - k_3)\mathcal{V} + k_1} \quad (17)$$

$$[W]_{\text{in}}^* = \frac{[X]_{\text{out}}\mathcal{V}(k_1k_4 - k_3k_4\mathcal{V})}{(k_3k_3 - k_3k_4)\mathcal{V}^2 + (k_4k_2 - k_3k_2 - k_3k_1)\mathcal{V} + k_1k_2} \quad (18)$$

where constants  $k_1, \dots, k_4$  are defined in the Appendix. Function  $\sigma(T_\mu)$  contains the non-linear term  $\Phi$  (5) from which  $\mathcal{V}$  cannot easily be isolated, and therefore the above result entails making a linear approximation of  $\Phi$  in terms of  $\mathcal{V}$ , also detailed in the Appendix.

When equations (17) and (18) are substituted into water balance equation (3) to find  $\mathcal{V}^*$  at which osmotic equilibrium (ii) is also present, a quartic equation in  $\mathcal{V}$  results (as opposed to a quadratic, before). This quartic equation is not stated, but the important point is that it has one viable solution which connects the steady state solutions for

<sup>1</sup>These unstable points have a Jacobian matrix with one zero and one negative eigenvalue.

Figure 3: Steady state  $\Phi^*$  for a bioreactor vesicle with  $N_c = 3$  MS channels, as  $[X]_{\text{out}}$  increases. Main figure: The presence of channels extend the  $[X]_{\text{out}}$  viability range of the reactor by around 70 fold, as compared to Figure 2. In region 1, channels remain closed, in region 2 (shaded) channels open in response to membrane tension and in region 3, channels are maximally open. Inset: Combinations of steady state  $X$  and  $W$  molecule numbers in the aqueous pool of the reactor, during the channels closed, channels opening, and channels maximally open phases. Parameters are identical to Figure 2, with MS channels active in the range  $0.85 > \Phi > 0.75$ .

$\sigma(T_\mu) = 0$  to the solutions for  $\sigma(T_\mu) = 1$  over the tension region  $T_0 < T_\mu < T_m$ , as illustrated in Figure 3, between the horizontal dotted lines. After tension  $T_m$  is exceeded, the system has again a fixed membrane permeability, and continuing to further increase  $[X]_{\text{out}}$  causes the catastrophic limit  $[X]_{\text{out}}^c$  to be passed (Figure 3, red vertical line), where the steady state of the system disappears. Figure 4 shows what actually happens to the dynamics of the three flows through the reactor, once  $[X]_{\text{out}}^c$  is passed.

If the channels of the reactor remain closed until a higher membrane tension, closer to the critical limit of  $\Phi = 1 - \epsilon = 0.5$ , then for the parameters used, the reactor suffers a negative discriminant (13) *before* the channels become active. This interesting situation is shown in Figure 5 and results in a small window of  $[X]_{\text{out}}$  values for which the reactor has two stable states. One stable state involves the channels being closed and the reactor remaining in a ‘low throughput’ mode. The other involves the channels being slightly open and the reactor in a ‘high throughput’ mode. It can also be seen that the reactor will exhibit hysteresis in switching between the two steady states as  $[X]_{\text{out}}$  is increased and decreased across this region.

To conclude the study, Figure 6 compares the viability region of a bioreactor with no channels to a bioreactor with MS channels, when  $[X]_{\text{out}} = 1.0\text{M}$ , for a large parameter space of diffusion constants  $D_X$ ,  $D_W$  and reaction rates  $k$ . Here, ‘viability’ means the capacity to hold a far from equilibrium steady state at the imposed external substrate concentration. It can be seen that inclusion of MS channels improves the viability range of the bioreactor for *intermediate* values of reaction rate  $k$  (middle left and middle right plots). Nevertheless, when  $k$  is high and the internal reaction fast (top left plot), the viability region  $D_X > D_W$  is very small indeed and the presence of channels (orange region) does not extend this much, meaning that the viability is similarly limited. Conversely, when  $k$  is low (bottom right plot), then MS channels are generally not required to maintain a steady state for the range of  $\{D_X, D_W\}$  combinations. Thus again, the two reactors have equal viability.

## Discussion and Conclusions

In this study, we aimed to model the simplest protocellular scenario where the action of MS channels could be explored. We found that our minimal system can exhibit at least two

Figure 4: Reactor dynamics when passing the catastrophic threshold. The rates of the three flows through the reactor in Figure 3 are shown, when (a)  $[X]_{\text{out}} = 3.2275\text{M}$  exceeds and (b) when  $[X]_{\text{out}} = 3.0725\text{M}$  does not exceed the catastrophic external substrate concentration  $[X]_{\text{out}}^c = 3.1569\text{M}$ . In both cases, red lines are the rate at which  $X$  enters the vesicle, green lines the rate that  $X$  transforms into  $W$  and blue lines the rate at which  $W$  leaves the vesicle. In (b) all three rates manage to become equilibrated in contrast to (a) where a small difference persists between them, leading to the accumulation of  $X$  and  $W$  inside the vesicle and eventual osmotic rupture. The stochastic simulation was performed with the Gillespie algorithm.

Figure 5: Bi-stability in the bioreactor with MS channels. Main figure: Steady states of the same bioreactor as in Figure 3, but now with channels activating at higher membrane tension  $0.525 > \Phi > 0.51$ . Inset: a zoomed view of the small bistable region on the left of the figure, showing two stable nodes exist in the range  $0.0429M < [X]_{\text{out}} < 0.0440M$ : one node is in the channels closed regime and the other is in the channels active regime.

interesting behaviours which were not obvious from the outset. The first is that the reactor can suddenly burst when the external substrate concentration reaches a critical concentration, even though it may be far from maximum membrane tension at that point. Secondly, we found that under some parameter regimes, the bioreactor with channels can have two viable steady states for the same external substrate concentration. In this scenario, perturbations applied inside the reactor could flip it like a toggle switch between a low throughput mode and a higher throughput mode.

Importantly, we observe that the bioreactor demonstrates the above behaviours only when substrate  $X$  is more permeable than product  $W$ , otherwise the reactor will remain spherical or shrink with increasing external substrate concentration<sup>2</sup>.

Our general hypothesis that MS channels would improve the stability region of the reactor was confirmed, but only partially. We found that high or low values of the reaction rate constant  $k$  bring about the same viability region, whether or not the reactor included channels. Only for intermediate values of  $k$  did having channels significantly widen the range of external substrate concentrations the reactor

<sup>2</sup>It must be noted when  $D_W \geq D_X$ , then for high  $[X]_{\text{out}}$ , even though the reactor is stable in principle, unrealistic molecule numbers could exist inside the vesicle volume, invalidating the well-stirred assumption in this domain.

Figure 6: Comparison of the viability of a bioreactor with no channels to a bioreactor with MS channels, over a region of parameter space. Each plot is for a different value of reaction rate constant  $k$ . For outside substrate concentration  $[X]_{\text{out}} = 1.0M$ : (a) dark green and light green areas indicate that both reactors have a steady state at the particular  $\{D_X, k, D_W\}$  parameter combination, with the dark green area indicating this stability is simply because the reactor does not actually go into a tension state ( $D_W \geq D_X$ ), (b) orange areas indicate where *only* the MS channels reactor has a steady state when  $[X]_{\text{out}} = 1.0M$ , finally (c) red areas show parameter combinations where neither reactor can achieve steady state for the imposed external concentration. Diffusion constants explored are  $\pm 95\%$  that of  $D_{\text{ribose}}$ . Model parameters are different from previous figures in that burst tolerance  $\epsilon = 0.1$  and in the reactor with channels, MS are active between  $0.92 > \Phi > 0.91$  ( $T_o = 0.8, T_m = 0.9$ ).

could handle.

We believe that our results might be of relevance to future work involving this type of membrane organization,

perhaps within the context of simple vesicles (such as liposomes) carrying transmembrane properties with MS properties. Owing to their simple but non-linear responses, MS open new avenues within the study of synthetic biological systems (Cheng and Lu, 2012; Maharbiz, 2012). Since MS channels can help to modulate the protocell response to signals, allowing them to achieve more complex behaviors (such as alternative steady states), and MS can also be modulated, for example, by means of light activation (Folgering et al., 2004), we conjecture that MS channels can play a role in implementing computational features in simple models or liposome computation (Smaldon et al., 2010).

## Appendix

In general, a linear approximation of  $\Phi$  (5) is not possible. However, for the small range of  $\mathcal{V}$  values that the channels are active, this approximation is reasonable. We can write  $\Phi = m\mathcal{V} + c$  where

$$m = \frac{\Phi_o - \Phi_m}{\mathcal{V}_o - \mathcal{V}_m} \quad (19)$$

$$c = \Phi_o - m\mathcal{V}_o \quad (20)$$

Constant  $\Phi_o$  is obtained by inverting (6) and setting  $T_\mu = T_o$ . In turn, constant  $\mathcal{V}_o$  is obtained by inverting (5) and setting  $\Phi = \Phi_o$ . Constants  $\Phi_m$  and  $\mathcal{V}_m$  are calculated in similar ways.

The constants used in (17) and (18) are:

$$k_1 = D_X S_\mu k_5 + D_c N_c k_6$$

$$k_2 = D_W S_\mu k_5 + D_c N_c k_6$$

$$k_3 = D_c N_c m$$

$$k_4 = k\lambda k_5$$

$$k_5 = \epsilon(T_m - T_o)$$

$$k_6 = 1 - T_o\epsilon - c$$

# How Fast Can We Evolve Something?

Inman Harvey

Evolutionary and Adaptive Systems Group  
University of Sussex, Brighton, UK  
inmanh@gmail.com

## Abstract

When applying a Genetic Algorithm to a new problem, how many generations should one reasonably expect to wait before reaching an acceptable solution? Using arguments based on information flow into the genepool, mediated by selection each generation, we present a rough and ready heuristic.

## The Problem

You have encoded a new problem for solution by Genetic Algorithm (GA) in what you hope is a sensible manner, using a population size and mutation rates that appear appropriate. Yet after 10,000 generations you are nowhere near reaching an acceptable solution; was that long enough to wait?

The textbooks and standard literature provide surprisingly little advice on this crucial matter. Using arguments inspired by information-theoretic approaches to evolution (Kimura, 1961; Worden, 1995), we present a crude Rule of Thumb. Primarily we are concerned with complex problems associated with a fixed high-dimensional fitness landscape, but we start by recasting the problem in terms of a childrens' game.

## The Game of Twenty Questions

For convenience, suppose there is a pre-agreed list of  $2^{20}$  objects from which Player 1 secretly picks one as the target. Player 2 may ask 20 binary questions ('animal or not?', 'bigger than a brick or not?') to try and identify the target; what is the best strategy? Ideally, each successive question should divide the currently remaining pool of possibilities exactly in half, so that Player 1's response reduces the remaining uncertainty of Player 2 by the maximum possible 1 bit of Shannon information. Any question that fails to divide the pool into halves will provide less information and may leave some remaining uncertainty after the 20<sup>th</sup> question.

This can be reformulated into a simplistic asexual GA. With a population size of  $2^{20}$ , the initial generation consists of one example of every possible target (that could be represented by different binary genotypes length 20). Each question corresponds to a generation with a round of truncation selection where the 'fitter' half of the population is selected, and then duplicated (without mutation) to maintain the same population size. After 20 such generations, if the selective 'questions' have been ideally posed, the final population should consist of  $2^{20}$  copies of the desired target.

Clearly the very maximum amount of information, passed through such 50% truncation selection into the population (or its genepool), is 20 bits in 20 generations.

A more realistic asexual GA will achieve significantly less than this 1 bit information flow per generation. Selection is unlikely to produce the ideal 50/50 split; also the population will typically be far smaller than the complete genotype space. Thus mutation must partially compensate by expanding the population each generation beyond the limited set of possibilities within the initial small population; this is at the expense of some information being lost from the genepool each generation. Hence, as Worden (1995) points out, the figure of 1 bit per generation counts as a speed limit, like the speed of light, that is an idealized upper bound; in practice, significantly fewer bits per generation are achievable.

Higher rates of selection such as 25% truncation selection would result in 2 bits per generation as this upper speed limit. But since there are other reasons (such as avoiding getting trapped on local optima) that tend to make higher rates undesirable, we focus here on the paradigm case of 50% truncation selection. This is equivalent to the most basic forms of tournament selection (Harvey, 2011).

**Redundancy.** The example of binary genotypes of length 20 does indeed imply a search-space of size  $2^{20}$ . However in evolutionary search we are often not searching for just one target genotype, but any one of an equivalence class that count as equally fit. In the game of 20 Questions, if the  $2^{20}$  possible targets actually fell into say  $2^{10}$  different equivalence classes, and the second Player can win by identifying the equivalence class rather than the unique target, then the initial uncertainty can be counted as 10 bits rather than 20 bits. This clearly reduces the number of Questions (or generations) needed.

## Does Recombination Change the Picture?

The implication so far is that an evolutionary problem phrased in terms of binary genotypes of length  $L$  should expect to need a minimum of  $L$  generations, adjusted by two estimated fudge factors. The first such factor significantly increases the generations needed; the role of a relatively small population and the loss of information due to mutations incurs considerable costs. The second such factor, arising from an assessment of the likely degree of genetic redundancy, may partially compensate by tending to decrease the generations needed. So far this assessment is based on an asexual GA.

But GAs are typically sexual, and many will expect the addition of recombination to provide a significant speed-up. Indeed, under some circumstances it definitely will.

Mackay (1999) argues that, under particular assumptions, recombination speeds up the asexual rate of 1 bit per generation (where he agrees with the argument above) to something of order  $\sqrt{L}$  bits per generation, where  $L$  is the length of a binary genotype. This is a massive speedup, and simulations based on those assumptions broadly confirm experimentally this factor that Mackay derives analytically.

But these assumptions are completely unrealistic for any problem where GAs are likely to be used. He assumes that fitness is a strictly additive trait; i.e. no epistasis with each locus on the genotype contributing fitness independently of the values at other loci. This can be considered a 'Mt. Fuji' fitness landscape; for such simple scenarios there are much more effective search algorithms than any standard GA.

For instance, consider a population of  $L$  clones of some randomly chosen genotype. Produce  $L$  new offspring, where the  $i^{\text{th}}$  one differs from the parent at the  $i^{\text{th}}$  locus, and compare the fitness of each one with its parent. This immediately identifies the fittest allele at each locus, and allows you to identify the peak of Mt. Fuji in a single generation. No real world GA application comes anywhere close to corresponding to such a simplistic fitness landscape, yet such assumptions of additive fitness are quite often used when biologists do theoretical population genetics. Why is this?

**Micro-evolution and Macro-evolution.** I believe the answer is that biologists very commonly consider issues of *micro-evolution*: they consider an already-evolved species of complex organisms and its ongoing 'struggle' to maintain its fitness through natural selection in the context of continual environmental and competitive challenges that tend to decrease that fitness. Loosely speaking, the fitness of any species, whether single celled amoeba or far more complex mammal, must be around unity if it neither goes extinct nor increases without limit. But this is like maintaining height through constantly climbing up (via natural selection) a downward escalator driven down by 'deterioration of the environment' in its broadest sense. This is the picture given by Fisher's Fundamental Theorem (Fisher, 1958), especially as clarified by Price (1972).

In such a scenario, where any evolved phenotypic trait probably depends on the sum of a number of genetic contributions, then the micro-evolutionary recovery from environmental deterioration may well justify the biologists' assumption of additive fitness. But the scenario faced by those using evolutionary algorithms is usually very different.

They are typically interested instead in *macro-evolution*: the equivalent of mammal species developing from unicellular species over billion of years. If this is characterized by extended periods of stasis, punctuated by individual innovations, for instance in the context of Neutral Networks (Harvey, 2001), then the additive fitness assumption ceases to make sense. One can agree (Ochoa and Harvey, 1999) that the more correlated a fitness landscape is, the more advantageous it is to add recombination. One can agree that recombination is still worth adding to a GA; its role appears largely to be mitigating the negative effects of mutation. But unless one buys into the wholly unrealistic assumptions of Mackay (1999) and others, in the absence of compelling evidence to

the contrary it seems prudent to assume that macro-evolution has the speed limit associated with an asexual GA.

## The Rule of Thumb

Let us first assume binary genotypes, and some standard GA with the equivalent of 50% truncation selection, recombination and appropriate rates (Harvey, 2001) of mutation. If your search-space corresponds to a 20-bit genotype, then 20 generations (at 1 bit per generation) is your starting point. This may be reduced by an estimate of the redundancy; if one plausibly thought that phenotype space partitioned into say  $2^{10}$  equivalence classes, this reduces the figure to 10 generations.

But then very significant allowance must be made for the relatively small population you are likely to be using, and the loss of information due to mutations. One order of magnitude would seem conservative for this, and I tentatively allow 2 orders of magnitude. I.e., for a 20-bit problem with 50% redundancy, I would recommend  $20 \times 0.5 \times 100 = 1000$  generations. For a steady-state GA with population size  $P$ , this is equivalent to  $1000 \times P$  new individuals.

**Real-valued genotypes.** When evolving (e.g.) neural networks, the weights may be encoded in doubles or floats rather than bits on the genotype. As a first approximation, decide whether e.g. 4-bit or 6-bit precision is likely to be adequate for the job, and this gives a direct conversion to the binary case. With a feed-forward network having, say, 3 nodes in the hidden layer, one should note that any perfect network is functionally equivalent with any relabeling of the hidden nodes, and this would give an immediate redundancy factor of  $3! = 6$ , and all such redundancy is helpful.

**Caution.** This heuristic suffers from many imperfections, from lack of knowledge of the details of any particular case, and from the need to make imprecise estimates. It should be treated with caution. Nevertheless, until more principled estimates are proposed it seems better than nothing.

# An Emergent Model for Mimicking Human Neuronal Pathways in Silico

Önder Gürcan<sup>1,2</sup>

<sup>1</sup>Ege University, Computer Engineering Department, Üniversite cad. 35100 Bornova, Izmir, Turkey

<sup>2</sup>Paul Sabatier University, Institut de Recherche en Informatique de Toulouse, 118 route de Narbonne, 31062 Toulouse, France  
 onder.gurcan@{ege.edu.tr,irit.fr}

In this study, our aim is to mimic human neuronal pathways without assuming the transition from microscopic to macroscopic scales depend upon mathematical arguments. Human neuronal pathways are natural *complex systems* in which large sets of neurons interact locally and give bottom-up rise to collective macroscopic behaviors. In this sense, correct knowledge of the synaptic effective connections between neurons is a key prerequisite for relating them to the operation of their central nervous system (CNS). However, estimating these effective connections between neurons in the human CNS poses a great challenge since direct recordings are impossible. Consequently, the network between human neurons is often expressed as a *black box* and the properties of connections between neurons are estimated using indirect methods (Türker and Powers, 2005). In indirect methods a particular receptor system is stimulated and the responses of neurons that are affected by the stimulus recorded to estimate the properties of the circuit. However, these neuronal circuits in human subjects are only estimations and their existence cannot be directly proven. Furthermore, there is no satisfactory theory on how these unknown parts of the CNS operate.

We propose a computational *emergent* model<sup>1</sup> that integrates the knowledge from neuroscience and *artificial self-organization* to derive from it the fundamental principles that govern CNS function and its simulation, and ultimately, to reconstruct the human CNS pathways in silico. The term *artificial self-organization* refers to a process enabling a software system to dynamically alter its internal organization (structure and functionality) during its execution time without any explicit external directing mechanism (Serugendo et al., 2011). Our *emergent* model uses temporal data collected from human subjects as an *emergent* macro-level description of the underlying neuronal pathway. Dynamic activity and spiking are modeled at the individual neuron scale. Consequently, the local information in the model is the knowledge about the behavior of individual neurons, such as generation of spikes and transmission of these spikes

to their postsynaptic neurons. The effect of a spike on a target neuron is defined as a temporal membrane potential change in response to the influence of a source neuron that connects to it. That influence is not instantaneous, and is delayed by the physical distance between neurons. However, the interactions of neurons that result in macro-level *emergent* behaviors are unknown and obviously neurons alone are not able to deal with this information. Thus, we defined *adaptive* mechanisms for individual neurons based on biological knowledge. Moreover, to be able to specify purely local information about the reference macro-level pattern, we used the peristimulus frequency (PSF) analysis method (Türker and Powers, 2005).

We model the neuronal network as a dynamic directed graph  $\mathcal{G}(t) = (\mathcal{N}(t), \mathcal{S}(t))$  where  $\mathcal{N}(t)$  denotes the time varying *cooperative* neuron agent (vertex) set and  $\mathcal{S}(t)$  denotes the time varying synapse (edge) set. The set of excitatory (resp. inhibitory) neuron agents at time  $t$  is denoted by  $\mathcal{N}^+(t)$  (resp.  $\mathcal{N}^-(t)$ ) where  $\mathcal{N}(t) = \mathcal{N}^+(t) \cup \mathcal{N}^-(t)$ . A synapse  $\{n, m\}$  delivers spikes from  $n$  to  $m$  with a delay of  $d_{nm}$  and with a synaptic strength of  $\eta$ . We denote the set of postsynaptic neighbors of a neuron agent  $n \in \mathcal{N}$  at time  $t$  as  $Post_n(t) = \{k \in \mathcal{N}(t) | \{n, k\} \in \mathcal{S}(t)\}$  and the set of temporally closest presynaptic neighbors as  $Temp_n(t)$ . The nominal behavior of neuron agents is *spike firing*. The *adaptive* behaviors of neuron agents are subjected to the non-cooperative situations of the agents which are propagated by the feedbacks (Algorithm 1). We denote the set of feedbacks as  $\mathcal{F}$  and we model sending a feedback  $f_a \in \mathcal{F}$  using an action of the form  $send(f_a, \mathcal{R})$  where  $a$  is the source of  $f$  and  $\mathcal{R} \subset \mathcal{N} \setminus \{a\}$  is the set of receiver agents. The *tuning behavior* of neuron agents is modelled using an action of the form  $tune(\{n, m\}, f)$  for  $n, m \in \mathcal{N}(t)$  and  $f \in \mathcal{F}$ , which correspond to the adjustment of  $\{n, m\}.\eta$  by  $f$  at time  $t$ . The *reorganization behaviors* of neuron agents are modeled using actions of the form  $add(\{n, m\})$  and  $remove(\{n, m\})$  for  $n, m \in \mathcal{N}(t)$ , which correspond to the formation and suppression (respectively) of  $\{n, m\}$  at time  $t$ . The *evolution behaviors* are modelled using actions of the form  $create(n, m)$ ,  $createInverse(n, m)$  and  $remove(n)$

<sup>1</sup>This model has been recently reported in (Gürcan et al., 2013, 2012).

for  $n, m \in \mathcal{N}(t)$ .  $\text{create}(n, m)$  corresponds to the creation of a neuron agent between  $n$  and  $m$  by  $n$  having the same type of  $n$ .  $\text{createInverse}(n, m)$  corresponds to the creation of a neuron agent between  $n$  and  $m$  by  $n$  having the opposite type of  $n$ .  $\text{remove}(n)$  corresponds to the suppression of the neuron agent  $n$  by itself.

**Algorithm 1** Response to the feedback  $f_m$  received at time  $t$  of neuron  $n$  where  $f_m \in \mathcal{F}_{if}$  and  $m, n \in \mathcal{N}(t)$ .

We applied the model to the reflex responses of single motor units obtained from conscious human subjects. The exact information we used about the underlying pathways is that *sensory neurons make monosynaptic connections with the alpha motoneuron*. In this sense, we considered this path as the shortest path in the underlying network and defined its duration as  $l$ . Therefore, we initialized the simulations as  $\mathcal{N}(0) = \{s, m\}$ ,  $\mathcal{S}(0) = \{\{s, m\}, \{m, \emptyset\}\}$  and  $d_{sm} = d_{m\emptyset} = l/2$  where  $s, m \in \mathcal{N}^+$  and  $l$  is the latency of the estimated beginning of the pathway.

The results show that (e.g., Figure 1), **the emergent neuronal network model learns to generate what is observed in human subjects in cellular resolution**. What makes the model promising is the fact that, to the best of our knowledge, it is the first realistic model to self-wire an artificial neuronal network by efficiently combining neuroscience with artificial self-organization. Although there is no evidence yet of the model's connectivity mapping onto the human connectivity, we anticipate this model will help neuroscientists to learn much more about human neuronal networks, and could also be used for predicting hypotheses to lead future experiments.

# Effects of inducer intake kinetics on the dynamics of gene expression

Huy Tran and Andre S. Ribeiro

Dept. of Signal Processing, Tampere University of Technology, P.O Box 553, 33101 Tampere, Finland  
andre.ribeiro@tut.fi

## Abstract

Many genes are only active following the intake of an inducer by the cell, via passive diffusive, positive, or negative feedback intake mechanisms. Based on measurements of the *in vivo* kinetics of intake and subsequent transcription events in *Escherichia coli*, we use stochastic models to investigate how the kinetics of intake affects both transient and near-equilibrium dynamics of gene expression. We find that the intake kinetics affects mean and variability of the transient time to reach the steady state of proteins numbers and also the degree of fluctuations in these numbers. Fluctuations in the extracellular number of inducers affects the variability of protein numbers at steady state in a degree that differs with the intake kinetics. Finally, changing the intake kinetics of an inducer of a genetic switch allows tuning the bias in the choice of noisy attractor. We conclude that the kinetics of inducer intake affects transient and near-equilibrium gene expression dynamics and, consequently, the phenotypic diversity of organisms in fluctuating environments.

## Introduction

To survive, cells must adapt to environmental changes, such as in the concentration of nutrients and toxics. Some of these changes can occur at rates faster than, e.g., the cell cycle, and thus require rapid adaptability from the cells. This adaptability may involve modifications in the kinetics of membrane-associated mechanisms (Sajbidor, 1997), metabolic rates (Talwalkar and Kailasapathy, 2003), or gene expression (Yamamoto and Ishihama, 2005; Allen and Tresini, 2000).

Studies suggest that organisms such as *Escherichia coli* can adjust the reception of some external signals. For example, in normal conditions, transcription of the genes of the *lac* operon (Elf et al., 2007; Hansen et al., 1998) is inhibited by the native *lac* repressor. When allolactose is present in the environment, it is absorbed by passive intake transport and triggers the expression of the *lac* genes. One of the proteins expressed, *lacY*, enhances the intake of allolactose further, thus forming a positive feedback. Such feedback mechanisms are particularly useful in saving cellular resources in periods when inducers are not present (Jacob and Monod, 1961). On the other hand, negative feedback

mechanisms are appropriate for, e.g., quickly pumping unwanted substances out of the cell (Schnappinger and Hillen, 1996). One example is the tetracycline intake system, as the tetracycline-induced proteins *tetA* actively transport the tetracycline out of cell (Beck et al., 1982).

A recent study (Megerle et al., 2008) showed that the timing of intake of inducers differs widely between cells in monoclonal populations of *E. coli*. Such variability in intake times was visible in the differing timings for the appearance of proteins in cells following the introduction of the inducer in the media even though, after a transient period, all cells exhibited the same rate of protein production. Another recent study (Makela et al., 2013) supported this hypothesis, by showing that there is a wide variability in the timing of activation of transcription following the appearance of the inducer in the media that is not due to noise in gene expression but causes high cell to cell variability in RNA numbers for long periods of time (i.e. longer than several cell cycles). This source of phenotypic diversity is likely to be of particular relevance in fluctuating environments (Acar et al., 2013; Ribeiro, 2008).

Here, using detailed stochastic models of gene expression and intake processes in *E. coli*, we investigate if differing intake kinetics results in differing kinetics of expression of the target gene both in the transient period for protein numbers to reach near-equilibrium, as well as in the subsequent stable phase. Next, we investigate how fluctuations in inducer numbers in the environment affect this variability. Finally, we investigate whether the intake kinetics of inducers can affect the behavior of a small genetic circuit, namely, a toggle switch.

## Methods

We compare the kinetics of expression when the inducer of the target gene enters cells via positive feedback mechanisms, passive diffusion, or negative feedback mechanisms. While varying the intake kinetics, the mean number of proteins expressed by the target gene is kept invariant in the stable phase.

The dynamics of the models is driven by the delayed

Stochastic Simulation Algorithm (delayed SSA) (Roussel and Zhu, 2006). This algorithm, unlike the original SSA (Gillespie, 1977), allows delaying the release of products, following a reaction. Furthermore, it differs from previous algorithms that can accommodate delays (e.g. (Bratsun et al., 2005; Barrio et al., 2006)) in that it can handle multiple delayed events in one reacting event, which facilitates the modeling of genetic circuits (Ribeiro, 2010). The delayed SSA uses a wait list to store delayed output events. The wait list is a list of elements (e.g., proteins being produced), each to be released after a time interval has elapsed (also stored in the wait list).

Each model includes an extracellular environment, which contains inducers, a cellular intake mechanism of inducers, and a gene expression mechanism that requires activation. The proteins produced can affect the intake kinetics, so as to model positive or negative feedback mechanisms. The models are simulated by SGNSim (Ribeiro and Lloyd-Price, 2007). All parameter values are extracted from measurements in *E. coli*, unless stated otherwise.

### Environment and passive transport of inducers

We assume that the inducers in the environment are inexhaustible. To model passive diffusion of inducers into cells, we set a rate constant of intake ( $k_{I_{in}}$ ) and an extracellular amount of inducers ( $I_e$ ) equal to 1, for simplicity. The intake is modeled by the following reaction:

where  $I$  is the number of inducers inside a cell. Note that, in all cases, even when an active mechanism is present, there is always passive intake.

To model fluctuations in inducer numbers in the environment, we assume that these follow a Gaussian distribution with standard deviation  $\sigma_e$  and unity mean. The fluctuations are set to occur at a rate slow enough to allow for one fluctuation to have a visible effect in the protein numbers before the next one occurs. For that, we use a first order autoregressive model to restrict the degree of change in inducer numbers from one moment to the next, with the following update rule:

$$I_e(t) = 1 - \phi + I_e(t - \delta t) * \phi + \epsilon_t \quad (2)$$

where  $\phi$  is constant,  $\epsilon_t$  is white noise with standard deviation of  $\sigma_t$ , and  $\delta t$  is the update interval. The model generates values for the extracellular inducer numbers according to  $I_e \sim N(1, \sigma_e^2)$ , where:

$$\sigma_e^2 = \frac{\sigma_t^2}{1 - \phi^2} \quad (3)$$

The inducers' extracellular concentration thus has the autocorrelation function's decay rate of  $-\ln(\phi)/\delta t$ . By tuning

$\phi$ , one can adjust the rate of change in this concentration. Finally, cells can dispose of inducers via diffusion, modeled as a first order reaction event:

Reaction 4 is assumed to account also for possible degradation events of inducers when inside the cell.

### Active transport mechanisms

We assume that the active transport rate is proportional to the number of proteins of the target gene. Let such transport be done by a protein  $P$ .

Positive feedback mechanisms are modeled by reaction 5a, where one inducer  $I$  is introduced in the cell by a protein  $P$ , while negative feedback mechanisms are modeled by reaction 5b, where one inducer is pumped out of the cell by a protein  $P$ :

These two mechanisms are never present simultaneously.

### Gene expression

We assume that the gene only expresses once activated. An inducer  $I$  interacts with the operator site  $O$  at the promoter region of the gene via the following reactions:

where  $k_a$  and  $k_d$  are the association and the disassociation rate constants, respectively. We assume half lives of inducers much longer than the expected time for disassociation to occur. Thus, we do not model degradation of inducers when bound to the operator. Additionally, we assume that leaky expression is negligible and that the operator site is not overlapped by the RNA polymerase for any significant time, so that the interaction between promoter and inducer is independent of the transcription process, particularly initiation.

The model of gene expression used was proposed and validated in (Ribeiro et al., 2006; Zhu et al., 2007), by comparing its kinetics with the real-time production of tsr-venus proteins under the control of a lac promoter in *E. coli* (Yu et al., 2006). The model consists of transcription (7), in this case of the activated gene, and translation of the resulting RNA molecules (8). Also modeled are first order degradation processes of RNA (9) (Bernstein et al., 2002) and proteins (10). Transcription events can occur when the operator-inducer complex  $O.I$  is formed. RNA polymerases are not explicitly modeled, as it is assumed that these exist in sufficient amount so that fluctuations in their numbers are not

significant. The transcription start site (TSS) is modeled explicitly so that transcription initiation events do not interfere with operator-activator reactions:

Reaction 7 describes the process of transcription. In particular,  $\tau$  (which follows a Gamma distribution (Kandhavelu et al., 2011)) accounts for the finding of a promoter region by an RNA polymerase, the formation of the closed complex at the transcription start site, the open complex formation, and finally, the promoter escape (DeHaseth et al., 1998) and elongation. Of these, in general, the most rate limiting steps are the isomerization steps and the open complex formation (McClure, 1985; Lutz et al., 2001). To model this multi-step process, we set the reaction rate to infinity, which causes the reaction to occur the moment the reactants become available. Thus, in this model,  $\tau$  determines the interval between consecutive productions of transcripts when the gene is induced.

Also, given the short duration of the elongation time in comparison to transcription initiation (Kandhavelu et al., 2011), the transcript ( $M$ ) is released at the same time as the TSS (i.e. the elongation time is assumed negligible). This allows for translation events of the RNA to initiate (reaction 8) as soon as the assembly of that RNA begins (Miller et al., 1970).

### Genetic Toggle Switch

The toggle switch consists of a network of two genes (here, B and C), whose proteins ( $P_B$  and  $P_C$ , respectively) repress the other gene's activity. We assume that these two genes are only active when bound by a protein produced by an operon, 'A', which is itself activated by the extracellular inducer. The transcription and translation processes in each of these genes are modeled as described in the previous section.

In this model, the operon A, once activated by the inducer, expresses two proteins,  $P_{A1}$  and  $P_{A2}$ . The former is involved in the intake of the inducer via a feedback mechanism (described in a previous section), while the latter activates genes B and C via the following reaction:

where  $P_{A2}$  is the activator,  $OR_i$  is an operator site at the promoter of either gene B or C in the inactive state ( $i = B, C$ ),  $k_a$  is the association rate constant, and  $O_i$  is the operator region with the activator bound to it.

The interactions between genes B and C form a switch. Namely, each of these genes, once activated by  $P_{A1}$ , is free

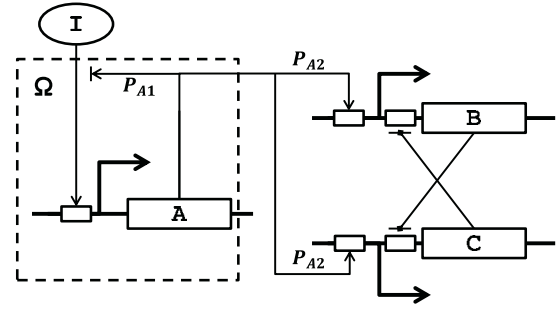

Figure 1: Model switch and activation mechanism. Inducers enter the cell by the intake mechanism, whose kinetics is determined by  $\Omega$  (dashed box). Protein  $P_{A1}$  is responsible for the feedback mechanism, while  $P_{A2}$  activates genes B and C, whose mutual interactions form a switch.

to express or to be repressed by the protein of the other gene ( $P_B$  represses gene C while  $P_C$  represses gene B). Such repressions occur at a second operator site at the promoter regions, via:

where  $P_j$  is the repressor,  $O_i$  is an active operator site of either gene B or C,  $O_i P_j$  is the operator region with a repressor bound to it, and  $k_{ai}$  is the association rate constant of that repressor. Importantly, this rate differs in the two genes, being higher for gene C, which biases the choice of noisy attractor made by the switch, when first initialized (Ribeiro and Kauffman, 2007). The noisy attractor favored is “gene C on and gene B off”. In Fig. 1 we show a schematic representation of this model.

### Characterization of the intake process

To compare the effects of different active intake systems we modeled these such that, for the same extracellular concentration of inducers, one has the same mean protein number of the inducible gene at steady state ( $[P]$ ), for varying active transport kinetics. To achieve this, the mean number of inducers in the cells at steady state ( $[I]$ ) has to be kept constant for varying intake kinetics, which is done by tuning the kinetics of passive intake.

In the stable phase, the influx and outflux rates of inducers are identical. Let  $f_1$  and  $f_2$  be the passive influx and outflux of inducers, respectively. These occur, respectively, via reactions 1 and 4. Given these,  $f_1 = I_e \times k_{I in}$  while  $f_2 = [I]k_{I out}$ . Let  $f_3$  be the flux due to the active transport. Since the flux ( $f$ ) from active and passive transports, in the stable phase, must equal zero, then:

$$\begin{aligned} f &= f_1 - f_2 + f_3 \\ &= [I_e]k_{I in} - [I]k_{I out} + f_3 = 0 \end{aligned} \quad (13)$$

The active transport flux  $f_3$  can thus be calculated as follows, in each condition:

$$f_3 = \begin{cases} [I_e][P]k_{P\text{ in}} > 0 & \text{positive feedback} \\ -[P][I]k_{P\text{ out}} < 0 & \text{negative feedback} \\ 0 & \text{passive diffusion} \end{cases} \quad (14)$$

Finally, we define  $\Omega$  as the log ratio between the passive disposal flux and the passive intake flux. The value of  $\Omega$  informs on the rate at which inducers are transported into cell by passive intake when in the stable phase:

$$\Omega = \lg\left(\frac{f_2}{f_1}\right) = \lg\left(\frac{f_3}{f_1} + 1\right) = \lg\left(\frac{[I]k_{I\text{out}}}{k_{I\text{in}}}\right) \quad (15)$$

$\Omega$  can take positive values in the presence of positive feedback (i.e.  $f_3 > 0$ ), and negative values in the presence of negative feedback ( $f_3 < 0$ ). Given passive intake alone ( $f_3 = 0$ ),  $\Omega = 0$ .

## Results

The models used to study the effects of the kinetics of the intake of inducers on the dynamics of gene expression are stochastic. Thus, to assert if their dynamics changes as a function of a parameter's value, we perform tests of statistical significance. Also, the models are initialized without any proteins of the target gene, so as to assess the kinetics both at the stable phase, as well as during the transient to reach the stable phase.

### Gene expression and intake kinetics

We first study the dynamics of protein numbers of a target gene as a function of the intake kinetics of the inducer, both in the transient phase and in the near-equilibrium or stable phase. In all cases, we use the following parameter values for the model of gene expression:  $k_P = 0.005 \text{ s}^{-1}$  (Taniguchi et al., 2010),  $d_M = 0.002 \text{ s}^{-1}$  (Bernstein et al., 2002), and  $d_P = 0.0005 \text{ s}^{-1}$  (Taniguchi et al., 2010). Also, we let  $\tau$  be a random variable following a gamma distribution  $\Gamma(\alpha, \theta)$ , with the shape  $\alpha$  equal to 2 (Kandhavelu et al., 2011) and the scale  $\theta$  equal to 25 s. The value of  $\theta$  was set so that, given the other parameter values, the mean RNA number in the stable phase is  $\sim 10$ , in accordance with *in vivo* measurements in *E. coli* (Taniguchi et al., 2010). The reaction rates of inducer-operator interactions are set to:  $k_a = 10^{-5} \text{ s}^{-1}$  and  $k_d = 0.02$ , so that the expected time for inducers to bind to the promoter is in accordance with measurements reported in (Elf et al., 2007).

We vary  $\Omega$ , while maintaining constant the mean protein ( $[P] \sim 30$ ) and mean inducer numbers within the cells ( $[I] \sim 1400$ ), when in the stable phase. For this, the range of variation of  $\Omega$  was constrained between -1 and 1. This range complies with measurements of the intake kinetics of known inducers (namely, of tet and lacY) in *E. coli* (Brown and Hogg, 1972; Hansen et al., 1998; Beck et al., 1982).

For each value of  $\Omega$ , we simulate 500 cells, each for 60 000 s, sampling their state every 60 seconds. We define the stable phase as the phase in which the mean protein numbers in the cells do not differ, in a statistical sense, for different values of  $\Omega$ . We found that all cells reach the stable phase after, at most,  $t = 4 \times 10^4 \text{ s}$ . In Table 1, we show the p-values of the Kolmogorov-Smirnov (KS) test comparing the distribution of mean protein numbers when  $\Omega = 0$  (passive intake) with each of these distributions for the other values of  $\Omega$ , in the stable phase.

Table 1: p-values of the KS test comparing the distribution of mean protein numbers when  $\Omega = 0$  and when  $\Omega$  takes other values, in the stable phase ( $t > 4 \times 10^4 \text{ s}$ )

| $\Omega$ | -1   | -0.4 | 1    | 0.4  | 1    |
|----------|------|------|------|------|------|
| p-value  | 0.03 | 0.19 | 1.00 | 0.26 | 0.34 |

The p-values from likelihood ratio tests with the null hypothesis that the distributions are identical are larger than 0.01, thus, we cannot reject that they are identical in a statistical sense. Therefore, in this range of values of  $\Omega$ , the models have identical mean protein numbers over time, in a statistical sense, when in the stable phase.

We next study the intracellular dynamics of inducer numbers as a function of  $\Omega$ . In Fig. 2a we show the mean number of inducers in the cells over time, from the start of the simulations. These vary significantly as a function of  $\Omega$ , before reaching the stable phase. In particular, for  $\Omega < 0$  (negative feedback), there is a rapid influx of inducers, followed by a steady decrease towards the numbers at near-equilibrium. For  $\Omega > 0$  (positive feedback), the inducer numbers take longer time to reach near-equilibrium. The passive intake mechanism ( $\Omega = 0$ ) is, of the cases modeled, the one for which the intracellular inducer numbers stabilizes faster. We found by inspection that this mean time is minimized for values of  $\Omega$  close to, but slightly smaller than 0. Finally, from Fig. 2b we observe that the proteins reach slower the numbers observed in the stable phase the greater is  $\Omega$ .

In Fig. 3, we show the mean transient time ( $t_0$ ) for each value of  $\Omega$ , along with the square of the coefficient of variation ( $CV^2(t_0)$ ), obtained from the multiple simulations in each condition. We find that the mean  $t_0$  is shorter for negative intake mechanisms. However, the  $CV^2(t_0)$  does not change significantly with  $\Omega$ .

Next, we assess the fluctuations in protein and inducer numbers in the stable phase as a function of  $\Omega$ . Fig. 4 shows the variance over the mean ( $\sigma^2/\mu$ ) ratio (i.e. the fano factor) of these numbers. This quantity is minimized for  $\Omega = 0$  in the case of intracellular inducer numbers. In the absence of feedback, these follow a Poisson distribution, as expected since both the passive intake and disposal are first-order processes. When there is an active feedback mechanism, the noise in protein numbers causes an noise in the intracellular

Figure 2: Mean numbers of inducers (top) and proteins (bottom) over time:  $\Omega < 0$  corresponds to negative feedback,  $\Omega = 0$  corresponds to passive intake, and  $\Omega > 0$  corresponds to positive feedback mechanisms.

Figure 3: Mean ( $\mu$ ) and  $CV^2$  of the transient time,  $t_0$ , for protein numbers to reach near-equilibrium as a function of  $\Omega$ .

Figure 4: Noise in protein and intracellular inducer numbers in the stable phase as a function of  $\Omega$ .

inducer numbers to be higher, then when only passive intake is present. The stronger the feedback mechanism (larger deviation from  $\Omega = 0$ ), the stronger is this effect.

On the other hand, the noise in protein numbers increases for increasing  $\Omega$ , being lower for negative feedback mechanisms and higher for positive feedback mechanisms. To investigate this, we calculated the normalized cross-correlation between protein and intracellular inducer numbers in the stable phase for varying  $\Omega$  (Fig 5). For positive feedbacks ( $\Omega > 0$ ), the protein and inducer numbers are positively correlated. This means that the noise in intracellular inducer numbers will be propagated to the protein numbers, causing it to be higher than in the passive diffusion case. In the regime of negative feedbacks, the numbers of intracellular inducers and proteins are anti-correlated, and the noise in the numbers of proteins is suppressed, when compared to passive diffusion case. Finally, as expected, in the absence of feedback mechanisms, the noise in intracellular inducer numbers does not affect the protein numbers, which is indicated by zero cross-correlation at  $\Omega = 0$ .

Finally, we study how the intake mechanisms behave in environments with fluctuating number of inducers. We assume that the extracellular number of inducers follows a Gaussian distribution with variance  $\sigma_e^2 = 0.2$  and unity mean, generated by the autoregressive model (see methods). We set  $\delta t$  to 30 s. We set the rate of environmental change,  $\phi$ , from 0.5 to  $\sim 1$ . The closer the value of  $\phi$  to 1, the slower the decay rate of the autocorrelation function of the extracellular inducer concentration. For  $\phi \sim 1$ , the extracellular inducer concentration is constant, corresponding to  $\sigma_e = 0$ . For each pair of values  $[\phi, \Omega]$ , we simulate one cell for  $5 \times 10^6$  s, sampling every 60 s. Fig. 6 shows the changes in fluctuations in protein numbers in the stable phase (as assessed by the  $CV^2$ ) due to the fluctuations in the inducer numbers, relative to when in stable environments.

From Fig. 6, with values of  $\phi$  larger than 0.8, the noise

Figure 5: Cross-correlation between protein and inducer numbers in the stable phase.

Figure 6: Noise amplification ratio ( $\sigma_P^2/\sigma_{P0}^2$ ) due to fluctuations in the number of inducers in the environment.

Figure 7: Noise amplification ratio ( $\sigma_P^2/\sigma_{P0}^2$ ) with  $\Omega = 1$ ,  $\sigma_e = 0.2$  for different values of  $\phi$ .

amplification in the protein numbers appears to increase with increasing  $\Omega$ . For each value of  $\phi > 0.8$ , we performed tests of statistical significance between the protein numbers when  $\Omega$  is 0, and when is -1 and 1, respectively. In both tests, we found that the distributions are distinct (p-values smaller than  $10^{-10}$ ), confirming that the increase in the noise amplification effect with increasing  $\Omega$  is statistically significant.

For positive feedback mechanisms, the noise amplification ratio for different values of  $\phi$  resembles a band pass filter (Fig.7). As  $\phi$  increases up to 0.9, the fluctuations in the external inducer numbers propagate more efficiently to the protein numbers of the induced gene (as shown in Samoilov et al. (2002)). When  $\phi$  increases beyond 0.9, the noise amplification ratio decreases as the positive feedback, affected by the extracellular inducer numbers, loses the ability to reflect the fluctuations in protein numbers. Interestingly, for  $\Omega = 1$ ,  $\phi = 0.5$ ,  $\sigma_e = 0.2$ , the protein  $CV^2$  is reduced by  $\sim 10\%$  when compared with the noiseless case (i.e.  $\sigma_e = 0$ ). This reduction is significant, namely the resulting distributions of protein numbers in the two cases are statistically distinct (p-value smaller than  $10^{-10}$ ).

### Inducible genetic switch

We study the behavior of a biased genetic switch as a function of the intake kinetics of an inducer. The model consists of two genes, B and C, which form a switch via mutually repressing interactions, and of a third gene, A, responsible for, once activated by the inducer, activate both genes B and C (figure 1).

In this model,  $P_{A_2}$  activates the expression of genes B and C in the same fashion as reaction 6, with the association rates:  $k_{A_2B} = 0.001 \text{ s}^{-1}$ ,  $k_{A_2C} = 0.002 \text{ s}^{-1}$ . The other parameters of genes B and C are:  $k_{PB} = k_{PC} = 0.05 \text{ s}^{-1}$ ,  $d_{MB} = d_{MC} = 0.002 \text{ s}^{-1}$ ,  $d_{PB} = d_{PC} = 0.0005 \text{ s}^{-1}$ . The formation of the open complex is regulated by:  $\tau_B, \tau_C \sim \Gamma(1, 100 \text{ s})$ . Finally, we denote  $[t_B]$  and  $[t_C]$  as the

Figure 8: Mean temporal difference between the first activation of genes B and C ( $\Delta t$ ), and bias in the choice of noisy attractor towards “gene C on” ( $C_{ON}$ ).

mean elapsed times from the introduction of inducers to the first closed complex formation in each promoter. The bias in the association rate constants biases the moments of formation of the closed complex. Namely, on average, these occur at moments that differ in time by:  $\Delta t = [t_B] - [t_C] > 0$ .

Given these parameter values, we observed that both noisy attractors of the switch are stable enough so that, once a noisy attractor is reached, the switch will remain there until the end of the simulation. Also, as noted in the methods section, the association rate of the activator protein  $P_{A_2}$  is higher in the case of gene C, which biases the first choice of noisy attractor of the switch. For  $\Omega = 0$ , the first noisy attractor selected by the switch will be “gene C on”  $\sim 65\%$  of the times (see Fig. 8).

We study the bias in the choice of noisy attractor as a function of  $\Omega$ . For each value of  $\Omega$ , we simulate 1000 independent cells, each in 30 000 s, sampled every 5 seconds. The results are shown in Fig. 8. From this figure, for increasing values of  $\Omega$ , the bias in choice of noisy attractor is reduced from  $\sim 67\%$  to  $\sim 62\%$ .

We performed statistical tests of significance comparing the distribution of  $\Delta t$  when  $\Omega = 0$  to the same distribution when  $\Omega = -1$  and 1 respectively. The test results show that all tested pairs of distributions are distinct (p-values smaller than  $10^{-10}$ ).

This result can be explained as follows. As  $\Omega$  is increased,  $P_A$  reaches the stable phase slower. Thus, both  $[t_B], [t_C]$  increase, but not by equal amounts (e.g. for half the number of proteins A, each of these times is doubled). Accordingly,  $\Delta t$  increases and the distribution of chosen noisy attractors becomes more biased.

## Discussion

Many genes in *E. coli*, as well as other single-celled organisms, only become active in response to an external signal,

either individually, or as part of a small network. Additionally, even when active, in the stable phase, most genes exhibit very small mean RNA numbers (from one to a few) (Taniguchi et al., 2010). This implies that differences in the intake time of inducers between sister cells can have significant implications on phenotypic differences between them. Similarly, differences in the kinetics of the intake process of different inducers may lead to significant differences on the mean and variability of response times to those inducers. Relevantly, Recent measurements *in vivo* showed that the intake time of inducers can be of the same order of magnitude as the cell division time and transcription initiation (Kandhavelu et al., 2011). The degree of cell-to-cell variability in these times is also equally high (Megerle et al., 2008; Makela et al., 2013).

Using a stochastic model with parameter values extracted from measurements in *E. coli*, we showed that the nature of the intake mechanism, that is, whether it is based on passive diffusion, positive feedback or negative feedback mechanism, has a significant impact on the dynamics of gene expression, both in the transient phase, as well as in the stable phase. The intake kinetics not only affects mean and variability of the transient time to reach the stable phase but also the degree of fluctuations in these numbers once it that phase. These effects are tangible in the behavior of small genetic circuits.

The results presented here show that the kinetics of the response, in terms of gene expression, of single-celled organisms to external signals, depends to great extent not only on the intake mechanism of the inducer/repressor molecule as well as on the mechanisms of transcription and translation. Also relevant is the observation that the intake mechanism also has an effect on the kinetics of gene expression, long after the transient period. This implies that the kinetics of genes responsive to environmental signals ought to be studied accounting for the effects of the intake mechanism on RNA and protein numbers dynamics. In the future, it would be of interest to further explore how active transport mechanisms, able of positive or negative feedback processes, can be used to tune the behavior and adaptability of small genetic circuits to fluctuating environments.

## Abstract

In this article, a four-cell CPG network, exploiting sensory feedback, is proposed in order to emulate infant crawling gaits when utilized on the NAO robot. Based on the crawling model, the positive episodic natural-actor-critic architecture is applied to learn a proper posture of crawling on a simulated NAO. By transferring the learned results to the physical NAO, the transferability from simulation to physical world is discussed. Finally, a discussion pertaining to locomotion learning based on dynamic system theory is given in the conclusion.

## Introduction

Crawling, as a type of quadrupedal locomotion, has been investigated on a number of humanoid robot platforms (Degallier et al., 2008) (Li et al., 2011). Compared to bipedal walking, crawling may be more versatile in terms of posture. For example, human beings can actually do *standard crawling* (knees and hands), *bear crawling* (feet and hands), *crab crawling* (upside down bear crawling), *leopard crawling* (a military specific crawling with elbows) (Wikipedia, 2013). Moreover, each of the crawling types differs regarding posture and needs specific training to perform. In this article, the work presented will focus on modelling *standard crawling* and training the NAO robot to learn the optimal posture.

From a bio-inspired perspective, central pattern generators (CPGs) are widely used in modelling locomotion on different robotic platforms (Ijspeert, 2008) (Harischandra et al., 2011) (Zhao et al., 2012), including humanoids (Degallier et al., 2008) (Endo et al., 2008). However, none of the above-cited work involves the posture optimization/learning for crawling and yet the posture determines the type of crawling. As far as CPG architectures are concerned, posture adjustment also plays an important role in the adaptability of CPGs (Grillner et al., 2008) (Orlovsky et al., 1999). Grillner et al (Grillner et al., 2005) not only posit that sensory feedback and postural control interactively connect the perceived environmental change to human neural structures via CPGs but also point out brainstem and basal ganglia are the

two main brain-related parts implicated in the adaptive solutions for locomotion. The latter theoretically implies the role of reinforcement learning (RL) as one possible implementable solution for presenting locomotion capabilities on humanoids.

RL provides an agent the capabilities of learning based on the interaction of the body, the environment and the neural structure. RL is one type of affective-modulation mechanism based on searching solutions for maximizing the reward-related value function (Sutton and Barto, 1998). Grillner et al's (Grillner et al., 2008) brain-based perspective on locomotion implies the role of RL in the adaptation of CPGs. Biologically, some scientists assume it accounts for the functions of basal ganglia in human brains (Wiering and van Otterlo, 2012). This neural-anatomic link hints that RL might also be implicated in locomotion and specifically, learning to crawl. Recently, the emerging new methods of continuous-space learning links machine learning closely to RL, such as continuous action space learning automaton (Cacla) and natural actor critic (NAC) (van Hasselt and Wiering, 2007) (Peters and Schaal, 2008). Both of these methods are used in different motor learning tasks on robots to update in a relatively high-dimensional parameter space (Kober et al., 2012) (Farkas et al., 2012). In our work, because of relatively high learning efficiency of NAC, it is used to figure out the optimal posture of crawling under the guidance of a specific reward function. RL, as an approach independent from traditional supervised and unsupervised learning, is a method which can seamlessly integrate scaffolding-related (supervised) and self-learning factors (unsupervised) into one process.

In this article, a posture learning architecture on a crawling humanoid is presented. In section 2, the main principles/theories pertaining to emulating infant crawling on a humanoid robot are introduced in detail, including the theories of CPGs and RL. In section 3, with the results from the simulation, the learned models are transferred to the physical robot for verification. The statistical results are given and analyzed. In section 4, a conclusion related to RL and learning locomotion is drawn.

## Methods and Theories

### CPGs and Crawling

Since crawling is a periodic motion, using CPGs to interpret and model it falls within the scope of the biological explanation of locomotion (Grillner et al., 2008) (Scott L Hooper, 2001). Via transferring this knowledge to robotics, it provides new methodologies for understanding morphology constrained locomotion principles on different robots (Ijspeert, 2008), including crawling robots (Harischandra et al., 2011) (Zhao et al., 2012) (Degallier et al., 2008). The approaches for modelling crawling can be classified into two categories: the engineering and the bio-inspired. Specifying the pre-defined trajectories of end-effectors, Aoi et al (Aoi and Tsuchiya, 2005) propose an engineering-based crawling model implemented on a bipedal robot. A key drawback of this approach is that this crawling robot might need recalculation and even remodeling when the environment changes, which limits motoric adaptation capabilities. On the basis of this, a lot of bio-inspired roboticists posit other solutions based on CPGs for avoiding the limitations of engineering methods. Nakamura et al, Righetti et al and Li et al (Nakamura et al., 2007) (Righetti and Ijspeert, 2008) (Li et al., 2013) together applied CPGs to locomotion by regarding sensory feedback as the input to reshape the output of neural controllers, endowing their architectures with *self-adaptation capabilities*. In this article, the CPG architecture based on sensory feedback reshaping is coined as *least sensory feedback CPG* model. The definition is as follows:

**Least Sensory Feedback CPG Model:** The adaptation and feasibility of CPG models reply on a limited/necessary number of sensors so that the output of the model can be interactively reshaped by perceived contextual change. The CPG architecture with above-mentioned characteristics is defined as the least sensory feedback CPG.

“least” here emphasizes necessary/minimal. For example, based on dynamic systems theory, Righetti et al propose the four-cell CPG network with necessary fast/slow transition feedback to implement standard crawling on the iCub robot (Degallier et al., 2008). Without fast/slow transition, the iCub cannot crawl in the real world. Inspired by Righetti et al’s model, we adopt the fast/slow transition into our experiments as a necessary self-modulation mechanism of CPGs.

**the mathematical model of CPGs** Inspired by work on iCub crawling (Degallier et al., 2008) and adapted from our previous work (Li et al., 2011), the Hopf oscillators are adapted into our work:

$$\dot{x}_i = a(m - x_i^2 + y_i^2)y - \omega_i x_i \quad (1)$$

Figure 1: Top: the limit cycles with and without transition feedback (Right and Left). Bottom-left: the four-cell CPG network. The round-head and sharp-head arrows represent negative (-1) and positive (+1) connection weights respectively. Bottom-right: The NAO robot and its correspondent joints under control of the CPG network for crawling.

$$\dot{y}_i = b(m - x_i^2 + y_i^2)x + \omega_i y_i + \sum_j \alpha_{ji} y_{ij} + F_i \quad (2)$$

$$\omega_i = 2 \cdot \pi \left( \frac{\omega_{swing}}{(1 + e^{-100y_i})} + \frac{\omega_{stance}}{(1 + e^{100y_i})} \right) \quad (3)$$

where the  $x_i$  is the output of the Hopf Oscillator and  $y_i$  is the internal state.  $m$  is the amplitude and  $a, b$  are the convergence rate ( $m=1$ ,  $a=1$  and  $b=5$  for all the experiments).  $\omega_i$  is the internal weight in this coupled oscillator. It is usually set to 1.  $y_{ij}$  is the output of the other cells except cell  $i$  and  $\alpha_{ji}$  is the external weight (from cell  $j$  to  $i$ ) of the four-cell network (Figure 1:bottom-left). Meanwhile,  $\omega_i$  also represents the frequency of this oscillator. Interestingly, by changing values of  $\omega_{swing}$  and  $\omega_{stance}$ , you can change the duration of increase and decrease rate of the oscillator. According to the statistical verification of Righetti et al’s model (Degallier et al., 2008), it is best to set  $\omega_{swing} = \omega_{stance} = 1.0$ .  $F_i$  is the fast/slow transition feedback which can be regarded as time-reset afferent feedback in the first layer of our previous model (Li et al., 2013) and defined as follows:

$$\begin{aligned} & \text{if } y_i > 0, y_i < 0 \text{ and } x_i \geq 0 \\ & F_i = -\text{sign}(y_i) * 50 \end{aligned} \quad (4)$$

$$\begin{aligned} & \text{if } x_i < -0.45, y_i \geq 0 \text{ or } x_i > 0, y_i \leq 0 \\ & F_i = -2\omega_i y_i - \sum_j \alpha_{ji} y_{ij} \end{aligned} \quad (5)$$

Where equation (4) describes the fast transition in which  $y_i$  decreases very quickly and equation (5) represents the slow transition in which the increase of  $y_i$  is delayed. Figure 1 (top) shows the comparison of limit cycles before and after adding fast/slow transition. The fast transition aims to control the robot to swing back quickly and the slow transition,

based on a triggered delay in the oscillator, is to smoothen the transition from stance phase to swing phase. These two characteristic types of feedback are activated by pressure sensors in the crawling iCub but maintained as invariant features in our work as the NAO robot does not have usable pressure sensors. They are regarded as types of proprioceptive sensory feedback related to the position of the joint. Then the investigation of crawling in NAO is transformed to the problem of how to find a proper posture that allows the robot to crawl with a crawling-featured “limit cycle”.

**Standard crawling and its key variables** Crawling, as the first milestone motion ability in human infants (Clearfield, 2004), serves as a cornerstone gateway to learn the body-environment interaction (Kail and Cavanaugh, 2012). Most expert crawlers during infancy move on knees and hands according to Righetti et al.’s investigation (Righetti et al., 2008). Hereby, in order to emulate standard crawling on a robot, the knowledge of how infants learn to crawl might be applicable. Clearfield et al (Clearfield, 2004) emphasize the salient role of spatial-temporal memory, especially the “distance”, in the process of infant crawling. Adolph et al (Adolph et al., 2012) found that the parental scaffolding by holding up crawling infants offers positive “safety” assurance on the posture. Therefore, it might be necessary to immerse two factors (distance and posture) into the learning mechanism. The posture can be embodied as the angle affecting the head direction (Figure 2). In our work, it is controlled by a Gaussian distribution between 30 degree and 50 degree.

The number of joints for a humanoid pertaining to the whole-body posture can be very high dimensional. To avoid high dimensionality, firstly, the robot begins in a crawling posture with which it stably mounts on knees and hands. Then only the necessary joints are taken into account for adjusting the crawling posture, including shoulders (pitch and roll), hips (pitch and roll) and elbows (roll). The knee and ankle joints are neglected as they do not move so much for crawling (Righetti et al., 2008).

### Natural Actor Critic in Posture Learning

**Episodic Natural Actor Critic (eNAC)** eNAC is well-known for its learning efficiency on searching optima in a continuous parameterized space. As the posture adjustment requires a continuous adaptation, eNAC is selected to optimize the crawling posture. Compared to Cacla, another efficient continuous-space RL, eNAC might suffer in possible failures by updating a parameterized model into an unknown action space (Wiering and van Otterlo, 2012). So a positive eNAC is applied in our work (for details see part 2) to highlight the potential failures.

NAC was proposed by Kakade et al (Kakade, 2001) and further developed and used in motor learning by Peters et al (Peters, 2007) (Peters and Schaal, 2008). It transforms the

traditional RL problem on solving the Bellman equation to an explorative process of linear regression. As a policy gradient approach, the principles of NAC are elucidated as follows:

Assume the stationary policy is  $\pi^\theta(\mathbf{x}, \mathbf{u})$  which can determine action space  $\mathbf{u}$  based on state space  $\mathbf{x}$  with a static distribution  $d^\pi(x)$ . The immediate reward is  $r(x, u)$ . Then the expected reward  $J(\theta)$  can be written as:

$$J(\theta) = \int_{\mathbf{x}} d^\pi(\mathbf{x}) \int_{\mathbf{u}} \pi^\theta(\mathbf{u}|\mathbf{x}) r(\mathbf{x}, \mathbf{u}) d\mathbf{x} d\mathbf{u} \quad (6)$$

$$\theta_{n+1} = \theta_n + \alpha \nabla_\theta J|_{\theta=\theta_n} \quad (7)$$

where the policy  $\pi^\theta(\mathbf{x}, \mathbf{u})$  is derivable at the policy parameters  $\theta$ , namely  $\nabla_\theta \pi^\theta$  exists. For maximizing expected reward  $J(\theta)$  with respect to  $\theta$ , the policy gradient will find the steepest increase direction  $\nabla_\theta J = J(\theta + \Delta\theta) - J(\theta)$  to update searching policy  $\pi^\theta(\mathbf{x}, \mathbf{u})$  until it converges.  $n$  represents the  $n$ th step of the update and  $\alpha$  is the learning rate (equal to 0.01). By and large, Equation (6) and (7) plot the rudimentary rule of thumb for policy gradient approaches. Transformed to natural policy gradient, Equation (6) and (7) can be revised to (8) and (9):

$$\nabla_\theta J(\theta) = \int_{\mathbf{x}} d^\pi(\mathbf{x}) \int_{\mathbf{u}} \pi^\theta(\mathbf{u}|\mathbf{x}) \nabla_\theta \log(\pi^\theta(\mathbf{u}|\mathbf{x})) \nabla_\theta \log^T(\pi^\theta(\mathbf{u}|\mathbf{x})) \mathbf{w} d\mathbf{x} d\mathbf{u} = F_\theta \mathbf{w} \quad (8)$$

$$\theta_{n+1} = \theta_n + \alpha F_\theta^{-1} \nabla_\theta J|_{\theta=\theta_n} \quad (9)$$

$$F_\theta = \int_T \pi^\theta \nabla_\theta \log \pi^\theta \nabla_\theta \log \pi^\theta d\theta$$

where  $F$  is the Fisher Matrix (FM). Multiplied by FM, normal policy gradient is changed to the steepest one (Here all the  $\mathbf{x}, \mathbf{u}$  are neglected for simplification reason).  $\mathbf{w}$  is a weight vector of the linear approximation and  $\nabla_\theta \log^T(\pi^\theta(\mathbf{u}|\mathbf{x}))$  is the group of basis functions. Then conclusively, by replacing  $\nabla_\theta J(\theta)$  in (9) with (8), the natural PG becomes:

$$\theta_{n+1} = \theta_n + \alpha \mathbf{w} \quad (10)$$

The RL problem changes from searching the steepest policy gradient to a normal regression problem with basis functions. Since the state-action function  $Q^\pi(\mathbf{x}, \mathbf{u}) = b(\mathbf{x}) + \nabla \log(\pi^\theta(\mathbf{u}|\mathbf{x})) \mathbf{w}$  and  $Q^\pi(\mathbf{x}, \mathbf{u}) = r(\mathbf{x}, \mathbf{u}) + \lambda \int_{\mathbf{x}'} p(\mathbf{x}'|\mathbf{x}, \mathbf{u}) V(\mathbf{x}') d\mathbf{x}'$  (where  $\lambda$  is the discounting factor,  $\mathbf{x}'$  is the next state,  $p(\mathbf{x}'|\mathbf{x}, \mathbf{u})$  is the probability of state transition.), assume the value function is  $V(\mathbf{x}) = b(\mathbf{x})$  and can be approximated by  $\psi^T(\mathbf{x}) \mathbf{v}$  (where  $\mathbf{v}$  is the weight vector and  $\psi$  is the vector of basis function related to the value function.) (Baird, 1993). Therefore, the approximation can be re-written:

$$\nabla \log^T(\pi^\theta(\mathbf{u}_t|\mathbf{x}_t)) \mathbf{w} + \psi^T(\mathbf{x}_t) \mathbf{v} = r(\mathbf{x}_t, \mathbf{u}_t) + \lambda \psi^T(\mathbf{x}_{t+1}) \mathbf{v} + \epsilon(\mathbf{x}_t, \mathbf{x}_{t+1}, \mathbf{u}_t) \quad (11)$$

if we sum up left and right side of equation (11), we get a straightforward regression problem for H episodes with s time-length:

$$\left(\sum_{t=1}^s \alpha_t \nabla \log^T(\pi^\theta(\mathbf{u}_t|\mathbf{x}_t))\right)_{1:H} \mathbf{w} + J = \left(\sum_{t=1}^s \alpha_t r(\mathbf{x}_t, \mathbf{u}_t)\right)_{1:H}$$

where  $J$  is the value-function related term considered as a constant baseline and  $\alpha_t$  is the average discounting factor. By means of the least square learning rule, the natural PG  $\mathbf{w}$  can be obtained for H episodes:

$$\begin{bmatrix} \mathbf{w} \\ J \end{bmatrix} = (\phi \phi^T)^{-1} \phi R.$$

$$\phi = \left[\sum_{t=1}^s \alpha_t \nabla \log^T(\pi^\theta(\mathbf{u}_t|\mathbf{x}_t)), 1\right]_{1:H}^T \quad (12)$$

$$R = \left[\sum_{t=1}^T \alpha_t r(\mathbf{x}_t, \mathbf{u}_t)\right]_{1:H}^T \quad (13)$$

where  $1 : H$  represent H times samplings within one trial (refer to details in the Algorithm).

**Implementation of the learning algorithm** Based on the above-mentioned proof (for details, please refer to (Peters, 2007)), the state space and action space are defined as  $\mathbf{P} \sim [P_{shoulder}, P_{hip}, P_{elbow}]$  and  $\mathbf{U} \sim [U_{shoulder}, U_{hip}, U_{elbow}]$ . So  $P = P_0 + U$ , where  $P_0$  is the initial posture vector. With the parametrized policy  $\pi^\theta(\mathbf{U}|\mathbf{P})$ , a posture can be learned via the optimization of the gaussian policy:

$$\begin{aligned} \pi_\theta(\mathbf{U}, \mathbf{P}) &= N(\mathbf{U}, \bar{\mathbf{U}}, \sigma) \\ &= \frac{2\pi}{\sigma} \exp\left(-\frac{(\mathbf{U} - \bar{\mathbf{U}})(\mathbf{U} - \bar{\mathbf{U}})^T}{\sigma^2}\right) \end{aligned}$$

where  $\mathbf{U}$  is the output vector of the policy and  $\bar{\mathbf{U}}$  is the input vector equal to the updated  $\mathbf{U}$  from last trial and  $\bar{\mathbf{U}} \sim [\theta_{shoulder}, \theta_{hip}, \theta_{elbow}]$ .  $\sigma$  is the exploration rate which determines the variance of  $\mathbf{U}$  from  $\bar{\mathbf{U}}$ . In our work,  $\sigma = 0.03$  as if  $\sigma > 0.05$ , the posture updating is unstable and if  $\sigma < 0.01$ , the posture adjustment is too insensitive and time-consuming.

The schema of eNAC algorithm is shown below:

**eNAC Algorithm:**

Repeat M trials each of which includes 10 rollouts (H=10), use the policy  $U_{1:H} \sim \pi_\theta(\mathbf{U}, \mathbf{P})$  to generate H groups of actions, each action is taken for time t=1,2,...s.

Calculate:

for each rollout, the episodic return  $r_i =$

$(\sum_{t=1}^s \alpha_t r(\mathbf{x}_t, \mathbf{u}_t))$   
the eligibility  $\psi_i = [\nabla \log^T(\pi^\theta(\mathbf{u}_t|\mathbf{x}_t)), 1]_i$   
then the gradient is:

$$\begin{bmatrix} \mathbf{w} \\ J \end{bmatrix} = (\phi \phi^T)^{-1} \phi R.$$

where  $R = [r_1, r_2, \dots, r_H]^T$  and  $\phi = [\psi_1, \psi_2, \dots, \psi_H]^T$   
Updating for each trial:

if  $\delta > 0$ , with  $\delta = R_{avg} - V_n$  where  $R_{avg}$  is the average of R and  $V_n$  is the episodic value function of last updating:

$V_{n+1} = V_n + 0.1 * \delta$  and  $\theta_{n+1} = \theta_n + \alpha \mathbf{w}$ , otherwise no updating.

Until the convergence condition is satisfied:  $\delta < 0$  all the time or  $\delta < |10^{-4}|$ .

It is noteworthy that, inspired by the Cacla architecture (van Hasselt and Wiering, 2007), the ‘‘positive updating’’ is used to avoid the inappropriate updating in the parameterized action space. Since the function approximation cannot accurately converge to the real Q function ( $\mathbf{w}$  cannot be zero), the convergence condition is necessary to determine the termination of each learning process.

## Experimental Setup

As mentioned in Section 1, the crawling distance and spine-line angle are the two important variables for evaluating the crawling posture (Figure 2). Accordingly, in RL, the reward function is composed of two terms ( $r_{distance}$  and  $r_{angle}$ ) related to the two factors that represent the two above-mentioned variables:

$$r_{reward} = r_{distance} + r_{angle}$$

$$r_{distance} = \exp\left(\frac{D}{2}\right) - 1$$

$$r_{angle} = \exp(e) - 1$$

$$\text{with } e = N(\mathbf{x}_0 = 1.05, \sigma = 0.1)$$

where D is the distance the robot crawls every episode. e is a Gaussian distribution with the center 1.05 (approximately 45 degree) and variance 0.1. As a matter of fact, distance is a very important measure of the improvement of crawling and spine-line angle is used to control and stabilize the body-height alteration.

In the experiments described below, the crawling CPGs are firstly implemented on a simulated NAO robot in Webots which is a popular commercialized robot simulator (Michel, 2004). Then the statistically-learned models are transferred to the physical robot for testing. The advantage of using the simulated robot is not only to avoid unexpected damage upon the physical robot but also to simplify the measurement of distance by using the special supervisor functions of Webots.

Figure 2: The standard crawling posture on knees and hands. The distance and spinline angle indicate the quality of crawling. The spinline angle is limited in a scope (30 degree~60 degree) by a Gaussian function.

### Experiment 1: Utilizing proprioceptive sensory feedback

This experiment is to verify the importance of proprioceptive sensory feedback (PSF) characterizing the crawling CPG. The snapshots of our crawling video (Figure 3) shows the utility of PSF. In this experiment, the NAO robot crawls with a manually-tuned posture. From the video(Li, 2013b), it is clearly observed that the NAO robot can crawl much further/faster with PSF. The multiple runs do not qualitatively effect the performance of crawling with possible simulated noise effects.

### Experiment 2: Learning the posture of standard crawling

With the crawling CPG and its proprioceptive sensory feedback, eNAC is applied on the simulated NAO robot for learning the optimal posture. Each episode of eNAC lasts 25s and the posture is continuously optimized by maximizing the crawling distance (in the same time duration) within the scope of the spinline angle. Each run of the experiment takes approximately 7 hours to converge (on a single Mac-Book pro). In total, 10 results are obtained statistically by running the experiment with variable values reset at the beginning of each run 10 times. Figure 4 shows the snapshots of optimized crawling and its comparison to the original one. Based on the video(Li, 2013c) and the snapshots, we can summarize the observable difference of two crawling gaits before/after learning. Firstly, before learning, the robot struggles to crawl forward with an obvious slippage on hands but after learning, the slippage disappears. Secondly, the crawling distance has been well optimized after learning. Subsequently, a detailed understanding of how the posture is adjusted by the eNAC is explained in the next section.

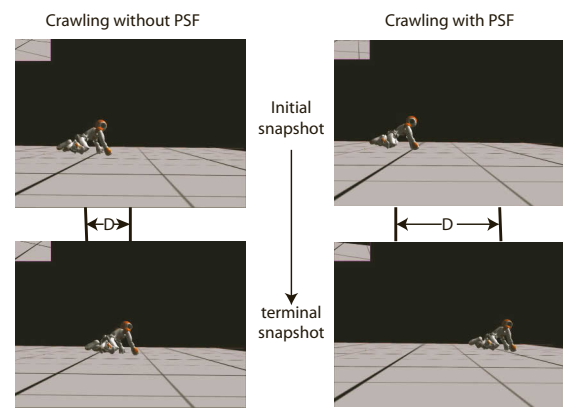

Figure 3: Left: the performance comparison of crawling without proprioceptive sensory feedback (PSF) between the initial and terminal snapshot (from top to bottom). Right: the performance comparison of crawling with PSF. D represents the rough measurement of the distance the robot crawls in the video. Both videos are shot from the same angle within the same time period.

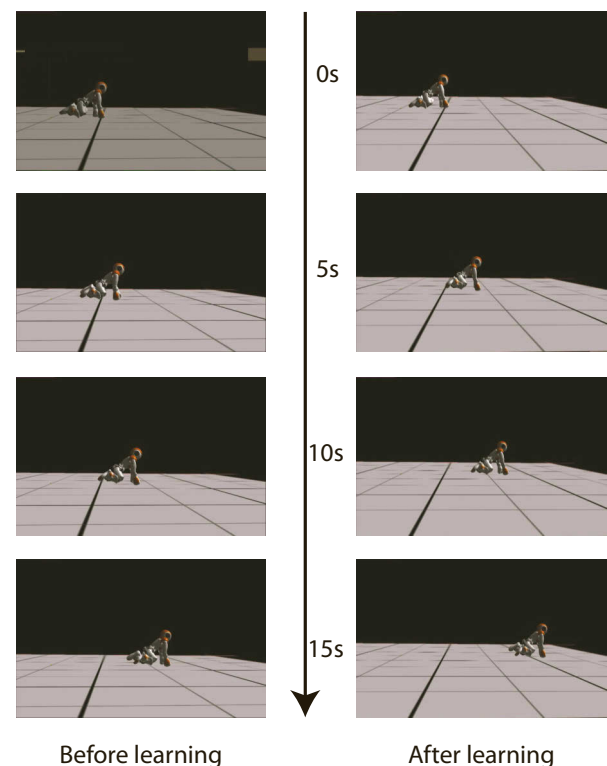

Figure 4: Left: the performance of crawling before learning. Right: the performance of crawling after learning. The left/right column snapshots are casted at the same time 0s, 5s ,10s, 15s and compared correspondently. The distance the robots crawls is labeled by three feature lines: one bold line (starting line) and two solid lines (distance mark lines).

Figure 5: The learning results of spine angle vs distance. The circle shows the values of  $r_{angle}$  and  $r_{distance}$  at the initial state. The cross points are the results after learning.

## Results and Analysis

### Results analysis

Since every run of each experiment starts independently from the same initial posture, it is intriguing to see how the statistical learning process tunes the six joints together and also if the 10 results are consistent. The typical characteristic of eNAC is that it can find the correct updating directions in the parameter space with a relatively high learning efficiency. Even though it might suffer in leading the updating into uncertain/invalid directions (Wiering and van Otterlo, 2012), the positive eNAC used in this article could possibly avoid this drawback. Figure 7.A~B show the increase of reward during the 10-run experiment. All 10 runs show the reward levels are boosted based on postural and distance rewards. Moreover, in almost every run of the experiment, the reward is effectively augmented during the first 20 episodes. This implies that positive eNAC could seek out valid updating pathways in a short time.

From the other point of view, the details of joint-value updating are highlighted in the Figure 7.C~H. Generally, even though different runs converge to distinct results (marked by black circles) within disparate updating episodes, the updating curves of each joint in every run share qualitatively similar update profiles and converge towards same directions. Therefore, above-mentioned conclusive summary insinuates the consistency over independent runs of learning processes. As a statistical learning approach, all the results obtained in the 10-run experiment are not the same. However, the converged posture adjustment values are located in a close scope. For example,  $\bar{\mathbf{U}} \sim [\theta_{HipYawPitch}, \theta_{HipRoll}, \theta_{HipPitch}, \theta_{ShoulderPitch}, \theta_{ShoulderRoll}, \theta_{ElbowRoll}]$  converges to the values approximately around 0.05 rad, 0.1 rad, -0.15 rad, -0.1 rad, -0.15 rad, 0.1 rad respectively (observed from Figure 7.C~H).

Figure 5 displays the improvement of crawling gait in two aspects. Compared to the initial state, the crawling distance and spine angle are both improved. In this article, the standard crawling posture is maintained by  $r_{angle}$  which defines the scope of spine angle. It somewhat stabilizes the crawling posture adjustment. In the experiment, it is observed that if the angular feedback mechanism is

Figure 6: The scorpion-like posture unexpectedly learned without the control of the spine angle.

omitted, the robot produces a crawling behaviour (flat scorpion-like motion) that does not conform to any typical infant crawling gaits (Figure 6). Although the scorpion-like crawling is an optimized solution in terms of only the distance, it is still considered to be an improper result as non-standard crawling posture. The crawling distance (in the same time duration) is a measure indicating the embodied improvement of crawling gait. The two different rewards are two reinforced drivers to make a proper crawling gait emerge.

### Transferrability to the physical robot

The 10 results obtained via eNAC are transferred to test on the physical robot. The transferability from the simulated robot to the physical robot is always a significant problem. The main reasons causing the failure of transferring are: firstly, the inappropriate physics engine might lead to distinct physical interaction in the simulator compared to the real world, including the collision detection which is very important for locomotion modelling. Webots uses a widely-used physics engine, ODE (Open Dynamics Engine (Michel, 2004)). It has attained reliable performance in robotic simulation, especially on locomotion-related tasks (Harischandra et al., 2011) (Degallier et al., 2008). Secondly, the difference in timing. The machine time might be different from the real time. In our work, the physical robot cannot crawl with the straightforward transferring from the simulated results. However, the crawling gait is successfully transferred by doubling the CPG frequency. It seems the numerical integration used to calculate CPG has a strong attachment to the speed of the machine, causing a difference in the CPG timing on different hardware. Therefore, in order to transfer the work in the simulator to the physical robot, the timing relation between the simulation computer and robot's hardware has to be identified.

Figure 8 shows the gait performance on the physical robot with one crawling step (for the video, refer to (Li, 2013a)). Authors tested 10 results of the learning. 7 out of 10 can successfully perform a smooth crawling gait. The other 3 failed as the low value of  $\theta_{ShoulderPitch}$  cannot allow the arm to lift above the ground completely when the two arms are alternating. The robot cannot crawl "smoothly" even though it can crawl nicely in the simulator. This might be caused by the difference between the simulated world based on the

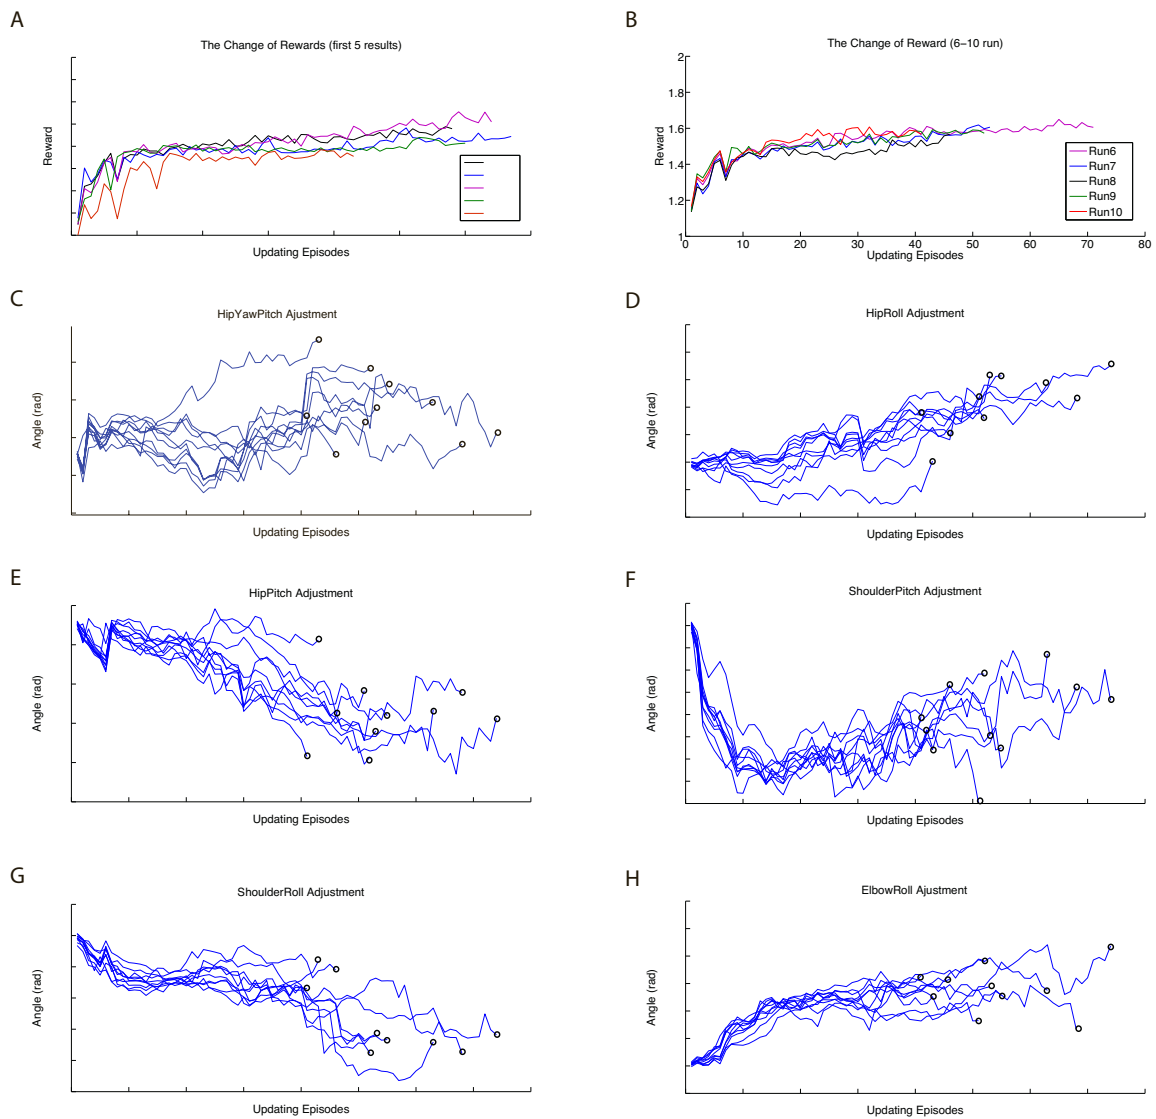

Figure 7: Figure 7.A~B show the reward increase of 10-run experiments. The "updating episodes" the episode which satisfies the updating condition of eNAC. Figure 7.C~H depict the change of joint values during the learning process and it covers the results of 10 runs for each joint. Those joints include HipYawPitch, HipRoll, HipPitch, ShoulderPitch, ShoulderRoll and ElbowRoll, the six joints affecting the quality of crawling gait. The black circles mark the converged points of each joint.

Figure 8: The implementation on the physical robot. This figure shows the video snapshot of one-crawling-step NAO robot on a wooden flat table (One crawling step means one time alternation of the supporting leg and arm.).

physics engine in Webots and the real physical world.

## Conclusion

In the previous two sections, we verified the necessity of proprioceptive sensory feedback and optimized postures for the crawling gait and tested the gait on the physical robot successfully. The results of experiments highlight the importance of sensory feedback and postural control for the CPG architecture. With a complete least-sensory-feedback CPG, the sensory feedback is designed to reshape the CPG output and the posture control is involved in shifting the oscillation centers of CPGs. Grillner et al.' work also implies these two functions in the CPG architecture(Orlovsky et al., 1999)(Grillner et al., 2008). Using eNAC, it assists the robot to learn/adapt on the ground of the interaction with the environment.

## Conclusion

### From Grillner's Inspiration towards Reality

Grillner et al's work on the theories of CPGs might be one of the most complete collections for CPG "huggers". His group not only investigate the biological theories of CPGs spanning from mollusc to man(Orlovsky et al., 1999) but also propose the plausible architecture of a goal-directed locomotion system which links CPGs to brain in an exact way(Grillner et al., 2005)(Grillner et al., 2008). This connection between the brain and CPGs is read as the connection between RL and oscillators in this article. RL fulfills the functions of basal ganglia and MLR (mesencephalic locomotor region) highlighted by Grillner et al(Grillner et al., 2008). The roles of CPGs include sensory-feedback integration and posture control. With the least-sensory-feedback concept, in this article, authors simply interpret roles of CPGs as the output reshaping and postural learning. Even though the crawling posture is successfully learned in our work, several questions still remain unsolved: Firstly, the least-sensory-feedback CPG model might not be the best solution to explaining sensory feedback integration. With pre-defined sensory feedback, even though the CPG model can acquire the adaptation in a lot of work(Li et al., 2011)(Li et al., 2012)(Li et al., 2013)(Nassour et al., 2013)(Nakamura et al., 2007), it is still functionally limited. If the sensor configuration is altered or the robot lacks necessary sensors (the case in this article), the CPG architecture might lose its adaptation to the changing environment. Therefore, a general solution for integrating sensory feedback may be demanded. Secondly, the energy efficiency of CPGs. Energy efficiency is a highlighted property of using CPGs(Tomoyuki et al., 2009)(Matsuo et al., 2012). Even though CPGs work as trajectory generators in our work, the energy efficiency is actually, at least, not high as the stiffness of joints is maintained as constant 0.9 (0~1.0 for the NAO robot). The link between energy efficiency and CPGs seems not be clear in theories. It might be a factor also related to morphologies. Since the

NAO robot has a rigid body, it might be difficult to achieve high energy efficiency.

## Rethinking locomotion learning

The focus of locomotion modelling has been gradually expanded into bio-inspired approaches(Ijspeert, 2008). Pfeifer et al emphasize the role of body morphologies as a core value of soft robotics(Pfeifer and Bongard, 2006). The locomotion learning/modelling has been elucidated as an interactive process instead of only being based on engineering approaches. The interaction of neural controllers, the body and the environment is the core of this ideology. From this angle, RL, as an interactive learning process, is able to bridge the three parts. Especially, with the newly proposed RL approached in continuous space, it can serve locomotion learning for more complicated parameterized models. This not only fits within the perspective of the architecture of Grillner et al's proposition(Grillner et al., 2008) but also is consistent with the theories of dynamic systems theory(Thelen, 1996).

## Drawbacks and Future work

Aside from the two major drawbacks mentioned above, the transferability from simulation to physical world is also an unresolved problem. In order to avoid this problem, the learning process should be able to transfer to the physical robot. In our work, the learning approach relies on the measurement of crawling distance. Webots proffers a convenient solution on any distance measuring with supervisors. In the physical world, the robot should have the ability to measure distance visually so that the learning process can be transferred. In future work, the motor primitive models(Kober et al., 2012) might be used to form a general solution to reshaping the CPG output. With this approach, the least-sensory-feedback model can possibly be adapted into a generic CPG model.

## Acknowledgment

The authors would like to thank the European Project Robot-DoC (<http://www.robotdoc.org>) for funding and providing help towards our work.

# An Artificial Behavioral Immune System for cognitive robotics

Ignazio Infantino and Riccardo Rizzo

Institute of High Performance Computing and Networking (ICAR), National Research Council (CNR), Palermo, Italy  
 ignazio.infantino@cnr.it, riccardo.rizzo@cnr.it

## Abstract

The paper proposes the implementation of an artificial behavioral immune system (ABIS) that could be integrated on a robotic platform. The ultimate goal is to have a form of perceptual processing to create the sensation of disgust (on more in general of discomfort) that may influence the behavior that is determined by the cognitive modules. The present work, being oriented to human-robot interaction, is focused on perceptual processing of facial expression, and speech recognition. As regards the first aspect, the human face closer to the robot is detected, then facial features are extracted, and finally a vector of data which has an emotional valence linked to expression is determined. The speech is processed to recognize the individual words and the moods using a "sentiment analysis" technique. An artificial immune system is used to recognize positive and negative "feelings" that comes from interactions and generate the signal of discomfort. For training and validation we used a few human subjects and sequences of a fairy tale.

## Introduction

The complex human immune system does not act only when it is attacked by pathogens, but it enables behavioral mechanisms aimed at preventing potentially dangerous situations. Some psychological processes are activated by the so-called behavioral immune system (Schaller, 2011; Schaller and Park, 2011), with the aim to anticipate and avoid risky situations. This system is essentially based on processing of perceptual cues (Stewart, 1993) and provides answers that influence emotions, behavioral impulses, and other cognitive mechanisms. The behavioral immune system has a direct influence on the social interactions of humans, and in particular can have a significant impact on: social gregariousness (or the opposite extraversion); prejudices, discriminatory or unsociable behaviors; mate preferences and mating behaviors; normative and counter-normative behavior. Regardless of the mechanisms of high-level cognition, binding between the behavioral immune system and the feeling of disgust and discomfort seems to be quite shared and accepted. Such mechanism, it is suitable for a possible experimentation "in silico", in an artificial agent such as a robot to carry out behaviors more similar to humans (Hutchison, 2012).

Among other bio-inspired computational models, the endocrine system (Timmis et al., 2009; Guorui, 2013; Pérez et al., 2012) and swarm computing (Timmis et al., 2010) have some similarities and common aspects with the model of the immune system, although for the moment lacking extensive experiments that will enable to compare them.

The functioning of the human immune system is the subject of study and research, not only in the biomedical field, but also in the field of computer science since it shows capacity of adaptation, learning and memory, and represents a model that produces cognitive functions like the neurons (Stewart, 1993).

Artificial immune system models used in data processing are rough simplifications of the immune network theory proposed by Jerne (1974). All these model are based on the binding between antigen (input data) and antibody of different kinds (potential solutions). Other aspects of the mechanism of the immune system, captured by the majority of the models, are clonal expansion, affinity maturation, apoptosis and clonal suppression (Castiglione et al., 1999; Cutello and Nicosia, 2006; Pavone et al., 2012).

In general, computational models of the immune system can be used as learning classifier systems (Vargas et al., 2003b,a; Castiglione et al., 2001; Cutello and Nicosia, 2002). In robotics, artificial immuno-genetic networks have been tested with success in various contexts (Raza and Fernandez, 2012); behavior arbitration in mobile robots (Ishiguro et al., 1995; Mochida et al., 1995); error detection (Canham et al., 2003); robot cooperation (Dioubate et al., 2008); short-term learning (Whitbrook et al., 2008); trajectory generation (Acosta et al., 2010).

One of the most used Artificial Immune Systems (AIS) model in data processing is aiNet, proposed in de Castro and Zuben (2000). This model can be considered as a modified evolutionary algorithm (Stibor and Timmis, 2007) and was adapted to many applications, for example in Ciesielski et al. (2006) the aiNet was used for text document classification. A similar problem was also faced in Stibor and Timmis (2007), where the aiNet algorithm was used to "compress" a set of input pattern distributions, in order to understand if it

is possible to use the developed aiNet in place if the original input pattern distribution.

The aiNet was also using for biclustering in de Castro and de França (2007), and in optimization problems as reported in Tsang and Lau (2012).

The paper proposes the implementation of an artificial behavioral immune system (ABIS) that could be integrated on a robotic platform. The ultimate goal is to have a form of perceptual processing to create the sensation of discomfort that may influence the behavior that is determined by the cognitive modules. In a previous work we have addressed the problem of creating a sort of artificial proprioceptive system and suitable for a humanoid robot, and we have achieved a cognitive capacity for introspection (Infantino et al., 2013). In the present work, being oriented human-robot interaction (Prado et al., 2012), we focus our perceptual processing on two important aspects: the detection of facial expression, and the speech recognition. As regards the first aspect, the human face closer to the robot is detected, then facial features are extracted, and finally a vector of data which has emotional valence linked to expression is determined (Breazeal, 2003). We evaluate the dynamic evolution of this signal for few seconds. The speech instead is processed to recognize the individual words, then it follows a "sentiment analysis" (Pang and Lee, 2008; Cambria et al., 2013) attaching a mood. As previous, some numerical parameters are mediated over a given time interval.

The artificial immune system is used to distinguish between pleasant and not-pleasant situations. Such discrimination arises from the distinction between self and not-self cells that is typical of the biological immune system, and it comes out from a training phase during the first stage of the life.

### The Artificial Immune System

The aiNet algorithm is one of most used and effective models (de Castro and de França, 2007). The most important part of the aiNet algorithm is a list of simulated antibody cells (Ab-Cells) that interact with the simulated antigens (Ag-Cells) in an  $R^n$  space: both have a pattern vector  $\vec{w}_{Ab}$  and  $\vec{w}_{Ag}$ . The Euclidean distance between  $\vec{w}_{Ab}$  and  $\vec{w}_{Ag}$  is used to represent the binding or the affinity among cells.

### The Simulated Antibody Cell

The antibody cell properties can explain a lot about the working of the whole immune system. In a simulated artificial immune system the antibody cell could be an object constituted by a vector and some behaviours. The template that characterize the antibody is called paratope, and it can match a specific part of the antigen called epitope. In the aiNet model these parts of the antibody are simulated using real vectors  $\vec{w}_{Ab}$  and  $\vec{w}_{Ag}$  and this match is measured using the euclidean distance:

$$dist(\vec{w}_{Ab}, \vec{w}_{Ag}) \quad (1)$$

this distance is a factor that modulates the mutation of the cell and the amount of generated clones.

Like the biological model, the mutation of the Ab-Cell is aimed to increase the match with the Ag-Cell so that the amount of mutation is lower if the match is high. The mutation is obtained by randomly change the value of components of the real vector that represents the paratope.

A cell that has an high match with the Ag-Cell generates a lot of clones in order to increase the response of the immune system to the antigens so that the distance in eq. 1 modulates also the number of clones produced from an Ab-Cell.

### The aiNet algorithm

The aiNet algorithm, as discussed in Stibor and Timmis (2007), is reported in algorithm 1 By mean of this algorithm, we identify the antibody cells with its weight set  $w_{Ab}$ , called  $\vec{b}$  for sake of simplicity.

In the aiNet model when an Ag-Cell is presented to the AIS the nearest Ab-Cells activates and are subject to duplication and mutation (clonal expansion). The mutated cells more similar to the input Ag-Cell are maintained, while the other generated cells are killed (during a process that is called affinity maturation). The selected Ab-Cells have a chance to be part of the "memory" of the system: a set of conserved cells that are used in the case of a new infection. This long term memory is represented by the cell set B in algorithm 1, while the sets C and M are a working memory, i.e. the set of cells created during antigenic presentation.

### AIS and self-not-self recognition

One of the interesting characteristics of the immune systems is that the antibodies are capable to distinguish the antigen cells from the cells of the host organism. This feature is called *self-not-self recognition*. According to Farmer et al. (1986) antibody cells that attack the organism are produced during clonal expansion but they are killed, by other antibodies, during the clonal suppression phase.

This mechanism requires a training phase aimed to recognize possible dangerous antibodies and how to eliminate them. Like antigens all the antibodies have an epitope that can be recognized by other antibodies, these epitopes are used during clonal suppression. Dangerous antibodies are recognized by using their epitopes and removed by other antibodies (Farmer et al., 1986). The training phase that allows to recognize the dangerous antibodies take place during the development of the embryo of the organism.

This model can be implemented in the artificial immune system by preceding the training session with a initial learning that involved only self cells: these cells are presented to the artificial immune system so that it can develop the antibodies that recognize these self cells. In fig. 1 and fig. 2 a toy example better explains self-not-self recognition: the input data are in fig. 1 and the self data, the blob on the top-left, are submitted to the system during the first part of the

**Algorithm 1** The aiNet algorithm

- 1: Random initialize a set of Ab-Cells with the vector templates  $B = \{b_1, b_2, \dots, b_N\}$
- 2: **while**  $t < t_{max}$  **do**
- 3:   **for** each antigen  $ag \in G$  with the vector template  $\vec{g}$  **do**
- 4:     split  $B$  in two parts,  $C$  and  $T$ ,  $|C| = n$ ,  $(C \cup T = B, C \cap T = \emptyset)$  by putting in  $C$  the  $n$  antibodies with minimum distance from  $\vec{g}$

$$C = \{\vec{c}_i \mid \text{dist}(\vec{c}_i, \vec{g}) < \text{dist}(\vec{t}_i, \vec{g}) \mid \forall \vec{c}_i \in C, \forall \vec{t}_j \in T\} \quad (2)$$

- 5:     **clonal expansion:** clone the cells in  $C$  according with their distance  $\text{dist}(\vec{c}_i, \vec{g})$
- 6:     mutate the cells  $c_i \in C$

$$\vec{c}_i = \vec{c}_i + \alpha * (\vec{g} - \vec{c}_i) \quad (3)$$

where  $\alpha = \frac{r}{\text{dist}(\vec{g}, \vec{c}_i)}$ ,  $r \in [0, 1]$

- 7:     split  $C$  in two parts,  $M$  and  $T_2$ ,  $(M \cup T_2 = C, M \cap T_2 = \emptyset)$  by putting in  $M$  the antibodies with

$$M = \{\vec{m}_i \mid \text{dist}(\vec{m}_i, \vec{g}) < \text{dist}(\vec{t}_i, \vec{g}) \mid \forall \vec{m}_i \in M, \forall \vec{t}_j \in T_2\} \quad (4)$$

with  $|M| = \psi * |C|$ ,  $|T_2| = (1 - \psi) * |C|$ ,

- 8:     **apoptosis:** remove the memory clones in  $M$  with  $\text{dist}(\vec{m}_i, \vec{g}) > \sigma_d$
- 9:     **clonal suppression:** remove clones  $m_j$  in  $M$  with  $\text{dist}(\vec{m}_j, \vec{m}_i) < \sigma_s$  with  $i \neq j$
- 10:     $B \leftarrow B \cup M$
- 11: **end for**
- 12:    remove from  $B$  all the cells  $b_j$  with  $\text{dist}(\vec{b}_j, \vec{b}_i) < \sigma_s$  with  $i \neq j$
- 13:    create new random antibodies in  $B$
- 14:     $t \leftarrow t + 1$
- 15: **end while**

Figure 1: A toy self-not-self problem. The pattern distribution top-left represent the self pattern; these patterns are presented to the AIS during the first step of the learning phase.

Figure 2: After the learning phase the AIS is ready to recognize self and non-self data. The antibodies not-self near the self Ab-Cells will be destroyed during the clonal suppression.

training session.

The AIS reacts creating a set of antibodies, in the following called *self antibodies*, that recognize the self cells. These antibodies are placed in the set  $B$ , the long term memory of the system. During the normal operation of the AIS antibody cells are produced: if these cells are near self antibodies they should be destroyed and a signal is generated. This mechanism is shown in fig. 3.

Using this schema it is possible to recognize a threat to the system because it is the one that generate antibodies of the type non-self, while any other organism cell will generate antibodies of the self kind, that will be immediately destroyed.

Figure 3: The structure of the system for self-not-self recognition. A signal is generated when antibodies self are activated.

### The Artificial Behavioral Immune System

The implemented system has been tested on the robotic platform NAO, and is an integral part of the behavioral system in the context of human-humanoid robot. The behavior comes from a cognitive architecture based on the model PSI (Cai et al., 2011), which in the past we have enriched with introspective capabilities (Infantino et al., 2013), with links between visual perceptions and emotions (Gaglio et al., 2011; Infantino et al., 2012; Infantino, 2012), and developing some creative capabilities (Augello et al., 2013b) by binding different perceptual representations. We have chosen two important sensorial stimuli that involve both high-level cognitive functions, and behavioral reactions influenced by the artificial immune system. Speech and facial expressions are two basic channels of communication in social interactions (see for example Prado et al. (2012), and Breazeal (2003)) both on a subconscious and rational level. The proposed system focuses on the detection and recognition of specific patterns from such perceptual stimuli that have a significant emotional impact (see fig. 4) The detection of words, the prosody, the tone of voice, and so on are all factors that influence social interaction (Pennebaker et al., 2003). The target robotic platform used for our experiments has a speech recognizer with detection of individual words and phrases. We have drawn upon an approach that mixes sentiment analysis and opinion mining (Cambria et al., 2013): to define the emotional content of a text, it is established a correspondence between word and five parameters: pleasantness, attention, sensitivity, aptitude, and polarity. The values taken by these parameters constitute the first part of the input of the immune system, and we consider it stored in long term memory by affective system. (see fig. 5). In a similar manner, we use some parameters extracted from facial expressions that typically allow you to classify it, and that are linked to patterns stored in the visual long term memory. Putting to-

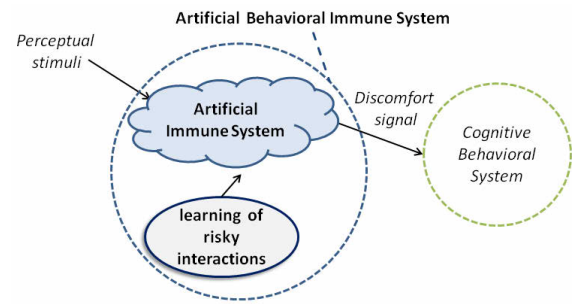

Figure 4: ABIS-schema

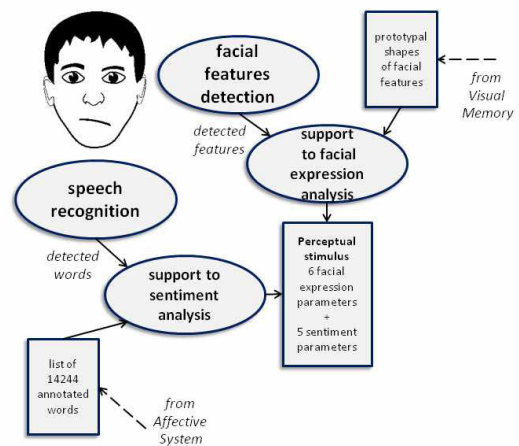

Figure 5: Perceptual processing

gether these two (processed) sensorial inputs, the immune system is trained to recognize risk situations. When a pattern is recognized potentially dangerous generates an alert that signals to activate typical behaviors of a uncomfortable situation. Of course, the cognitive behavioral system will be affected by this alert, but this could be ignored or hidden by the high-level planning and reasoning (see fig. 4).

### Speech sentiment analysis

The experimental setup is constituted by a human subject that directly speaks to the robot. The robot reacts emotionally based on the content of the speech and facial expressions detected in sync. As previously mentioned, the emotional content of speech is characterized by five numerical parameters resulting from publicly available semantic and affective database (MIT-Media-Laboratory, 2013). The database used contains 14244 concepts, and it is possible queried it by web. For example, the page <http://sentic.net/api/en/concept/smile/> corresponds to a xml file that contains the related concepts (sneer, start-laugh, hear-joke, smile-laugh, giggle), and numerical values of the parameters (pleasantness = 0.997, attention = 0.0, sensitiv-

ity = 0.0, aptitude = 0.0, polarity = 0.332).

## Face expression analysis

To characterize facial expression we used the six coefficients of Animation Units (AU) by using an API widely used in the context of face tracking (Microsoft, 2013). They are a subset coefficients defined in the Candide3 model (Ahlberg, 2001) that uses 87 2D points on the face to track a human head. From these six values it is possible to classify the facial expression considering seven basic expressions: neutral face, upper lip raised, jaw lowered, lip stretched, brow lowered, lip corner depressed and outer brow raised. The range of these coefficients is between -1.0 and 1.0. For example, the first coefficient indicate the lips movement, the value +1 indicates the lips completely opened and -1 completely closed. The afore-mentioned six coefficients can be used to classify an emotional state through a series of IF-THEN rules and a set of threshold values.

## Experiments

To validate the proposed approach we have designed an experiment that seems simple: the robot listens to a fairy tale and observes the facial expressions of the narrator. The data collected in this phase are used to train the immune system by means of a semi-manual labeling. A fairy tale being aimed at children, typically uses simple words and facial expression in the narrative is essential to strengthen the emotional content of the story (Alm et al., 2005). As with children, the robot can learn from a fairy tale a behavioral and emotional model on which to base its cognitive development. The learned model, in our case via the artificial immune behavioral system, can be employed to deal with normal interactions with humans. In the testing phase in fact a human speaks of a farm, a vegetable garden, animals, arousing emotions to the robot derived from having listened to the famous *The Tale of Peter Rabbit* by Beatrix Potter. The robot watched a video of this tale available on the web (Socratica, 2013). The narrative is divided in 35 sequences, each corresponding to a part of speech and a sequence of facial features detected (see fig. 6).

Figure 7 shows the maximum, minimum, and average (blue dashed line) of the parameters of sentiment for the 35 sequences.

For the learning phase of the six AU parameters derived from facial features are grouped by similarity (using a simple k-means), and clusters are labeled manually as negative or positive inputs. Figure 8 shows the average values of the Animation Units derived from facial features detected for the 35 sequences.

Preliminary experiments show a rate of correct recognition of discomfort situations of about 70%.

Figure 6: Perception example of sequence 5 of 35

## Conclusions and future work

The robot as a child could learn how to recognize positive and negative situations by visual and voice interaction with a tutor. In the article we proposed a low level mechanism that activates the alarm signals relating to the discomfort. It is inspired by the human immune system, and is based on the influences that such a system has on behavior.

We are conducting more extensive experimentation that allow us to understand how to improve the artificial immune system, integrating other perceptual signals, and optimizing the learning phase.

## Acknowledgements

We thanks Federico Corrao for the experimental setup. Financial support of the research is partially given by Ministero dello Sviluppo Economico e Innovazione (MISE), bando "MADE IN ITALY", project MI01 00424.

## Abstract

This paper reports on latest results from a larger research program trying to understand the computational principles behind the processing, acquisition and evolution of spatial language. Here we explore an evolutionary explanation of spatial landmarks by carrying out detailed computational experiments. The paper discusses the necessary mechanisms for representing different strategies involving landmarks, their effect on success in communication and their impact on the formation of spatial relations.

## Introduction

A lot of agent-based models examining evolution of language are dealing with (single-word) lexical systems such as the formation of colour terms (Steels and Belpaeme, 2005). There are some examples that try to go further and focus on the evolution of grammar, such as van Trijp (2008). However, those approaches typically start from predefined lexicons. The same holds for spatial language where early work has focussed on lexicons (Steels, 1995) and recent work has touched upon grammar (Spranger and Steels, 2012). This paper presents intermediate work that tries to bridge the gap between purely single-word lexical systems and more grammatical systems where words take on particular functions.

We are examining locative phrases consisting of spatial relations and landmarks. Here is an example of such a phrase from German.

(1) *der*        *Block*        *rechts*        *der*  
       the.NOM block.NOM right.PREP the.GEN  
*Kiste*  
       box.GEN  
       ‘The block to the right of the box’.

The phrase encodes a specific way of construing reality by integrating a number of spatial *strategies*. The phrase combines the *projective* spatial relation “rechts” (right) with a landmark – an inanimate object denoted by the phrase “der Kiste” (the box). The speaker explicitly *marked* the landmark (not obligatory).

The precise usage of landmarks in a language is culturally negotiated. In English inanimate objects can be used as landmarks. Other languages restrict landmarks to animate objects or only humans, and in some cases just to trees (Levinson (2003)). Moreover, the strategies for expressing conceptual choices – lexicon and grammar – differ across languages (Svorou (1994)).

Cultural diversity of spatial language strategies is the prime argument for cultural evolution of language (Evans and Levinson, 2009). Recently, a number of attempts were made at explaining the cultural evolution of spatial language such as toponyms (Schulz et al., 2006), the role of perspective – “me” and “you” – (Steels and Loetzsch, 2008), the origins of conceptualization strategies (Spranger, 2011) and grammar (Spranger and Steels, 2012). In this paper we focus on the role of landmarks including perspective but also inanimate objects. As the methodological framework we follow standard methodology for evolutionary explanations in biology (Tinbergen, 1963). In particular, we try to answer questions about processing, function, acquisition and evolution of spatial landmark systems.

## Experimental Setup

We employ a *language game* paradigm (Steels, 2012) in order to study spatial language use and evolution. Two robots from a population are trying to draw each others attention to objects in the environment using language. Figure 1 shows an example setup.

The environment consists of a number of blocks of equal size and color (circles), boxes (rectangle) and interlocutors (arrows). The vision system of each robot tracks objects in the vicinity and establishes a model of the environment consisting of blocks (circles) with real-valued distances and orientations of objects with respect to the body of the robot. The environment is open-ended. New blocks, boxes and robots are added or removed and their spatial configuration is changed.

1. First the robots establish a joint attentional frame (Tomasello (1995)). Subsequently, each agent scans the environment and establishes a situation model of the present

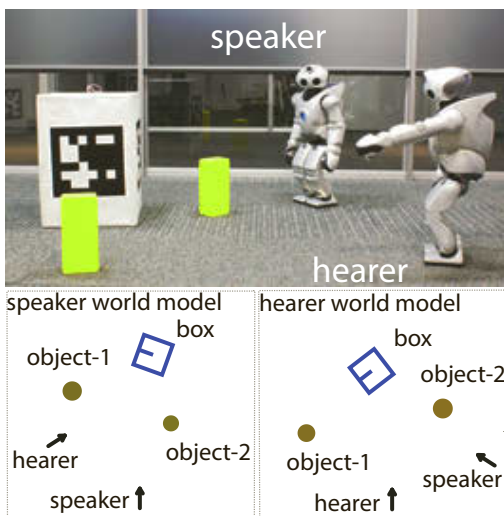

Figure 1: This figure shows the set-up for spatial language game experiments. The images left and right show the internal situation model as perceived by each robot.

objects and their position.

2. One of the robots is randomly assigned the role of speaker. The speaker randomly selects an object from the situation model (further called the topic  $T$ ). The speaker tries to find a discriminating spatial relation applied to a particular landmark or perspective for describing  $T$ . Subsequently, the speaker looks up the words he associates with the spatial relation and (possibly) the landmark and produces an utterance. For instance, he might say “links kiste” (roughly: left of the box) if the robots operate a German lexicon<sup>1</sup>.
3. The hearer looks up which relation and landmarks is associated with the words in the utterance. He examines his situation model to find out whether there is a unique object which satisfies the spatial relation with respect to the landmark. The hearer then points to this object. If no landmark is specified, the hearer might try different possible landmarks and see if there is a combination of spatial relation with landmark that is discriminating an object best.
4. The speaker checks whether the hearer points to  $T$ . If the hearer pointed correctly the game is a success and the speaker signals this outcome to the hearer. If the game is a failure, the speaker points to the topic  $T$ .

<sup>1</sup>Notice that there is no grammar in this phrase. Also, the landmark can be omitted.

Obviously things can go wrong in these interactions especially if the agents are in the process of building a language to succeed in these interactions. The speaker might not have an appropriate spatial relation to discriminate the topic from the rest of the objects in the situation model. Possibly, he has no word for denoting the landmark he has in mind which can lead to confusion with other landmarks and consequently with other objects in the situation model. On the hearer side, the robot maybe does not know certain words in the utterance. Lastly, the hearer might point to the wrong object. These situations present opportunities to update in particular to acquire new words and also expand internal language representations.

## The Role of Landmarks in Spatial Language

To give an evolutionary explanation of a phenomenon entails to give an account of the role the trait plays for the evolutionary success. For us, *communicative success* is the primary selective force in cultural language evolution. Consequently, we have to identify the role of landmarks with respect to that evolutionary pressure.

We use spatial language games to measure what is the impact of landmark systems on communicative success. Populations of agents are given different language and conceptualization strategies and we measure their performance in multi-agent simulations. In all populations agents are using *projective* spatial relations equivalent to English “front”, “back”, “left” and “right”. The relations are defined as a similarity functions which are computed from the difference in angles between an object and the prototypical angle of the category (Spranger, 2012). We compare 5 populations.

**egocentric (ego)** Agents use a single spatial relation in each utterance which is always interpreted egocentric to each robot. For instance, if the speaker conceptualizes “left” to refer to an object, the hearer will interpret the relation from his perspective.

**perspective, unmarked (pp, um)** Agents use the perspective of themselves but also of the other robot (Steels and Loetzsch, 2008, similar to). Upon hearing the term “left” the hearer retrieves the best possible interpretation taking into consideration his own and the other robot’s perspective on the environment. Similarly, the speaker might use an utterance such as “left” but refer to a position left of the hearer rather than left of himself.

**perspective, marked (pp, m)** Agents are using different perspectives but also clearly marking which perspective was used. For example, the speaker might say “left you” to indicate spatial relation and perspective.

**landmarks, unmarked (lm, um)** This population can use perspective (robots) and allocentric landmarks (the box), in conceptualizing reality. They do not communicate which object was used as a landmark.

Figure 2: Results for populations of 10 agents tested in different experimental conditions. For each result agents interacted 2000 times. Every successful interaction counts with 1.0, otherwise with 0.0. These scores are averaged over all interactions.

Figure 3: Examples of spatial scenes from each experimental condition ordered from left to right as in Figure 2. Left, for instance, agents (black arrows) share a similar perspective on the spatial scenes, there are always 2 objects per scene (circles) and no box. To the right the most difficult condition is shown. Agents have differing perspectives, there are on average 11 objects and there is a box.

**landmarks, marked (lm, m)** Same population as *landmarks, unmarked*. But, agents express which landmark they use in all utterances.

Figure 2 shows communicative performance of each population in different experimental conditions. Each condition consists of many spatial situations each of which include two robots and blocks whose positions change. But, the conditions differ in 1) whether a box is present, 2) the average number of objects and 3) the typical perspective of robots (see Figure 3).

The results show that agents capable of using different perspectives and landmarks perform better in communication than agents without. The effect increases the more objects are in each spatial context and the more the viewpoints of the interlocutors on the scene diverge. This is because agents which can use different landmarks are much more flexible. They have more choice of relation-landmark pairs and often can choose one that fits best or better for discrimination. There are three important observations. First, if the environment is simple and agents have a similar perspec-

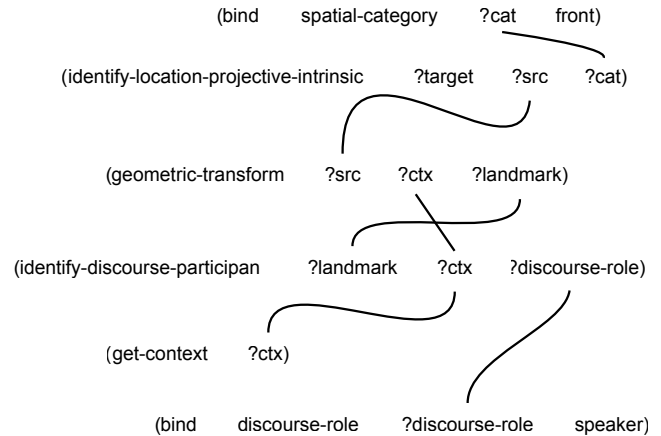

Figure 4: Representation for a speaker centric conceptualization.

tive on the scene, it is sufficient to use egocentric interpretation of phrases. Second, the best strategy is to use any landmark possible (both robots and allocentric landmarks). Third, marking which landmark or perspective was used always outperforms the unmarked case in which agents use different landmarks but cannot express them.

## Representing Spatial Strategies

We use a computational formalism called *Incremental Recruitment Language* (IRL) to represent the different strategies of conceptualising reality. IRL represents semantics as a constraint program. Programs consist of pointers to data items and operations on these data items. Figure 4 shows an example of such programs for a speaker centric conceptualisation such as in “vor mir” (in front of me). The program consists of pointers to the category *front*, and the discourse role *speaker*. Both are introduced via so called *bind*-statements. The other items in the program are functions linked via variables (starting with ?). For instance, *get-context* introduces the situation model computed by the vision system.

Spatial relations are implemented following ideas in cognitive semantics (Herskovits, 1986) and prototype theory (Rosch, 1975). We implemented two types of categories, distance-based (proximal) and angle-based (projective and absolute). We only focus on projective categories in this paper. Projective categories have a focal region around a specified axis. Similarity of some location to an angular category depends on the distance of angles. For instance, the *front* category has a high degree of applicability along the frontal axis. The following equations defines the degree of applicability, i.e. similarity,  $\text{sim}_a \in [0, 1]$  given an object  $o$  and an angular category  $c$  and a parameter  $\sigma$  which steers

the steepness of the function.

$$\begin{aligned}\text{sim}_a(o, c) &:= e^{-\frac{1}{2\sigma_c} d_a(o, c)} \\ d_a(o, c) &:= |a_o - a_c|\end{aligned}$$

$a_o$  denotes the angle of the position of  $o$  to the coordinate center and  $a_c$  is the prototypical angle of  $c$ .

Besides spatial relations, the program also contains operations. Operations take input parameters and compute new output parameters.

`get-context` fetches the situation model from the vision system of the robot.

`identify-location-projective-intrinsic` takes a spatial relation and an input set and finds the single object that best fits the category.

`geometric-transform` takes an input set and a landmark and transforms the input set so that the spatial positions and orientations are seen from the landmark.

`identify-discourse-participant` takes a discourse role such as `speaker` and `hearer` and identifies the interlocutor denoted by the discourse role.

Earlier work has examined how aspects of these strategies can evolve autonomously in populations of agents (Spranger, 2011). In the experiments presented in this paper, agents are assumed to have such strategies. They are given to the agents.

## The Formation of Spatial Relation Systems

We can now examine which operators are necessary for the formation of spatial category systems. Given a strategy and a set of invention, adoption and alignment operators concrete systems of spatial relations arise in populations of agents (Spranger, 2012). The following paragraphs detail the operators.

**Invention:** *Speaker cannot find a discriminating spatial category in production*

- **Diagnostic:** When the speaker cannot conceptualize a meaning (step 2 of the spatial language game fails).
- **Repair:** The speaker constructs a spatial relation  $R$  based on the relevant strategy (projective) and the topic pointed at. The new category is necessarily based on the distance or angle observed for the topic object (the initial sigma is small 0.1). Additionally, the speaker invents a new construction associating  $R$  with  $s$ .

**Adoption:** *Hearer encounters unknown spatial term  $s$*

- **Diagnostic:** When the hearer does not know a term (step 3 fails).
- **Repair:** The hearer signals failure and the speaker points to the topic  $T$ . The hearer then constructs a spatial relation  $R$  based on the relevant strategy and the topic pointed at. Additionally, the speaker invents a new construction associating  $R$  with  $s$ .

**Category alignment** Projective categories are represented by prototypical angles. After each interaction agents update the prototypical angle to better reflect the new observation by averaging the angles of objects in the sample set  $S$ . The new prototypical angle  $a_c$  of the category is computed using the following formula for averaging angles.

$$a_c = \text{atan2} \left( \frac{1}{|S|} \sum_{s \in S} \sin a_s, \frac{1}{|S|} \sum_{s \in S} \cos a_s \right) \quad (2)$$

The new  $\sigma$  value  $\sigma'$  which describes the shape of the similarity function of the category is adapted using the following formula.

$$\sigma'_c = \sigma_c + \alpha_\sigma \cdot \left( \sigma_c - \sqrt{\frac{1}{|S| - 1} \sum_{s \in S} (a_c - a_s)^2} \right) \quad (3)$$

This formula describes how much the new  $\sigma_c$  of the category  $c$  is pushed in the direction of the angle standard deviation of the sample set by a factor<sup>2</sup> of  $\alpha_\sigma \in [0, \infty]$ .

**Lexicon alignment** Its possible that a single agent can name the same category with different spatial terms. This phenomenon is called synonymy. Allowing agents to track synonymy in their lexicons can be beneficial for overall lexicon size, but only if agents have additional mechanisms for coping with it. Such a mechanism, called *lateral inhibition*, was introduced in Steels (1995):

- In case the interaction was a success both speaker and hearer reward the winning construction – the one used in production and interpretation – by a score of  $\delta_{\text{success}}$ . Competing constructions are punished by  $\delta_{\text{inhibit}}$ . There are two types of competing constructions. First, there are those constructions which associate the same spatial relation but with a different word. Second, there are constructions that link the same word to different spatial relations.
- After a failed game, both speaker and hearer decrease the score of the used association with  $\delta_{\text{fail}}$ .

<sup>2</sup> $\alpha$  is given by the experimenter and in all experiments described here  $\alpha = 0.5$

Figure 5: Results for a formation experiment in which agents develop a projective category system using a single landmark strategy (the box is used as landmark) in simple environments. Only few objects are present.

Figure 5 shows results for the formation of a projective categories. The population consists of 10 agents. an experimental run lasts 10000 interaction. Experimental runs are repeated multiple times and a number of measures tracked for confirming the convergence of the system.

**Communicative Success** tracks how successful the population is. After each interaction, it is checked whether speaker and hearer interacted successfully. Success is counted as 1.0, failure as 0.0.

**# Categories, # Constructions** is a measure for the average spatial relation inventory size and the number of constructions (number of words) known to the agent. These can diverge in case of synonymy and when there are words not denoting spatial relations but landmarks.

**Interpretation similarity** measures how similar the meaning of words are. Each agent tracks spatial relations without ever having access to the exact representation of all other agents. This measure compares the spatial relations of each agent based on how similar they are. 0.0 means no similarity. 1.0 would mean that all agents have exactly the same categories.

The results in Figure 5 show that agents can indeed go from no systems of spatial relations to one that is successful. In this case the population agrees on 3 categories on average. The little overshoot of constructions vs categories in the beginning is caused by synonymy that is later removed by the alignment operators.

Figure 6: Dynamics of a population of 10 agents which develop a spatial category system (egocentric strategy) of 5 spatial relations in the *similar pp, 2 obj, no box* condition (5000 interactions, 8 trials). At the same time the spatial relations align across the population (see rise in *interpretation similarity*).

## The Formation of Spatial Relation Systems and Landmarks

Next, we apply the insights from category formation and systematically study the effect of landmarks on such systems. We re-use the populations introduced in the previous section. All spatial relations (and terms) are removed from agents and instead they are provided with the language change operators described in the previous section.

Figure 6 shows the dynamics of these operators over time. Agents start without spatial relations and spatial terms. Gradually they invent and align their linguistic repositories. At the same time the population becomes more successful in communication. Figure 7 compares different populations in a number of experimental conditions (same as used earlier). When agents do not have the means to use landmarks they fail in developing successful systems of spatial relations (if the environment is complex). Again the populations which can express the landmark they are using are outperforming agents which cannot. Agents which can use the full scope of landmarks (me/you/box) available in scenes outperform those which can only use perspective (me/you) which outperform those that can only use an egocentric strategy.

Notice, how *landmark, unmarked* performs worse than the *perspective, unmarked*. The reason is that, upon hearing a new term agents have to adopt it using a particular landmark. This decision is essentially random, because agents were given no other means of deciding. The *landmark, unmarked* population has more landmarks to choose from. Therefore, agents are more likely to choose wrong. This makes clear that intermediary stages are necessary and that

Figure 7: Comparison of different populations forming spatial relation systems (same experimental conditions as in Figure 2, 8 trials). Every population consists of 10 agents which first develop a spatial language system (5000 games) and then their communicative success is measured (2000 interactions).

perspective strategies are suitable intermediaries.

### Evolving Spatial Relations and Landmark Lexicons

Lastly, we turn our attention to whether a lexicon of landmark terms and spatial relations can form simultaneously. Figure 8 shows results for an experiment where agents initially do not have words for landmarks nor do they have spatial relations. The Figure shows that agents can evolve both at the same time.

The following is an example utterance one agent in such a population uttered after 5000 interactions. The agent is using a category that he developed which behaves similarly to “front” and a new word for denoting the box.

- (4) *waketo tabeta*  
category-3 box  
‘to the front of the box’.

### Discussion

The results in this paper suggest two things. First, landmark systems provide a clear communicative advantage over non-landmark systems (shown for projective categories). This means that there is a selective pressure for developing landmark systems for spatial relations such as projective. Second, landmark systems can be culturally negotiated in a population. In particular, we provided simple invention, adoption and alignment operators sufficient for in silico evolution of landmark systems in populations of agents.

The results hint at possible intermediate evolutionary stages. For instance, unmarked cases always perform bet-

Figure 8: These populations form a system of projective spatial relations and words for marking perspective and landmarks. There is a difference between the average number of words (*# constructions*) and the average number of spatial relations (*# categories*). These are the words denoting landmarks or perspective.

ter than egocentric but worse than marked cases. This is an interesting result before something can be named it has to be conceptualised. In other words, before something can be named as a landmark it needs to have the potential to become a landmark. The unmarked systems therefore provide a necessary stepping stone for marked systems. Another similar example can be found comparing perspective-only to full landmark systems. Using perspective is always less successful than using everything as landmarks. This hints at possible evolutionary trajectories from animate to inanimate landmarks.

The spatial languages evolved in this paper are more or less developing in a vacuum. In the real world, different syntactic and semantic systems and strategies within a language interact and influence each other (Levinson and Wilkins, 2006, provide overviews of different strategies). How to understand and model these interactions remains an open issue although there is some initial work in this direction for colour (Bleys, 2010) and space (Spranger, 2011).

### Acknowledgements

This work was supported by Sony CSL Tokyo and Sony CSL Paris. I am grateful to Masahiro Fujita, Hideki Shimomura and the team at Sony Corporation for making the Sony humanoid robots available for the research discussed in this paper. I thank Luc Steels for help with the robot setup.

**Abstract.** Much can be learned about the progress, fathers and future of a scientific domain from the analysis of a collection of relevant articles and their corresponding authors. Here, we study the highly interdisciplinary domain of Artificial Immune System (AIS) since its birth, a couple of decades ago. We apply Social Network Analysis to the co-authorship network of the most comprehensive publicly accessible AIS bibliography. We automatically extract publication dates and author names from the bibliography and evaluate authors with the highest degree (unique collaborations) and centrality (influence).

Our results highlight the relative growth of publication volume and identify significant contributors in the AIS field. Furthermore, our findings are not only encouraging for the AIS community but may be useful for analyses of other scientific communities and leading contributors therein.

**Keywords:** Artificial Immune Systems, Social Network Analysis, Co-authorship, Information Extraction, Text Mining

## 1 Introduction

Artificial Immune Systems (AIS) are adaptive systems, inspired by theories and observed principles of the immune system, and applied towards solving computational problems [1]. Common AIS techniques are based on specific theoretical models explaining the behavior of the vertebrate adaptive immune system such as negative selection, clonal selection, immune networks and dendritic cells [2]. AIS are mainly classified into two categories: The first one aims at mathematically modeling the immune system to better understand its behavior. The second one uses the immune system as a metaphorical inspiration to engineer algorithms that are capable of learning and solving a huge variety of machine learning problems such as classification, clustering and regression analysis.

AIS is a relatively new field which began in the mid 80's with the modeling and refinement of Jerne's immune network theory [3] by Farmer et al. [4], and later by Bersini and Varela [5, 6]. However, it wasn't until negative selection was used by Forrest [7] for protecting computer networks from viruses that the AIS domain was established. Cooke and Hunt [8, 9] adapted immune networks for classification and Timmis [10] further improved it while De Castro et al [11, 12] worked on aiNet for multimodal function optimization and data analysis. The first book on AIS was edited by Dasgupta in 1998 [13].

In the past few years, several review papers have discussed the slow advances in AIS and proposed improvement strategies through novel and simpler AIS models (inspired by the vertebrate innate immune systems and immune systems of plants) as well as the development of a unified architecture for integration of existing models [14, 2, 15, 16]. Timmis argues that AIS has reached an impasse [2] and Timmis et al pointed out a dearth of theory to justify the use and continuity of AIS [17].

The domain of AIS has existed for a couple of decades but has never been analyzed quantitatively. Furthermore, the fear that the domain is stagnating was only based on qualitative studies targeting specific AIS models and frameworks, such as negative selection, clonal selection and more recently, the danger theory.

In this paper we use techniques from co-authorship network analysis and statistical methods in order to investigate the current state and future of the domain of AIS. Moreover, we identify leading contributors to the field using co-authorship network analysis and discuss our results. In the following section, we discuss the methods used for information extraction and statistical analysis, in addition to social network analysis of the co-authorship network. In section 3, we illustrate and discuss the growth of the AIS domain and compare it to the general growth of Medline indexed articles in general. Finally, in section 3.3, we discuss our results and the future directions of the field.

## 2 Methods

We adopt data mining techniques in order to extract author names and publication dates from the most comprehensive AIS bibliography [18] comprising 1044 articles and 994 authors. We only had access to a binary PDF format of the bibliography and therefore we had to convert it into an ASCII textual format. The converted text was far from the desired clean structured text and therefore a significant amount of manual curation was involved in order to systematically mark the end of the authors' list before automating the extraction of author names.

Publication dates are limited to the year of publication consisting of a 4-digit number  $YYYY$  where  $1980 < YYYY < 2010$  in order to avoid confusion with other numbers such as digital object identifiers (doi), volume numbers and serial numbers. More challenging was the task of author name extraction with some authors having their first names abbreviated others having full first names and others not respecting the first-name-last-name order. We manually restructured

the bibliography, ensuring that last names were preceded by abbreviated or full names. We prepended shared last names with the abbreviated first names to avoid the risk of agglomerating authors with a common last name. For example “X Lee” and “Y Lee” are considered two distinct authors and represented as: X-Lee and Y-Lee, respectively. Still, we face the possibility that two different authors would be counted as one if they share both lastnames and firstnames (at least initial). However, that is outside the scope of our analysis.

## 2.1 Social Network Analysis

Social Network Analysis (SNA) has played major roles in many disciplines in the past few years [19,20]. Co-authorship Networks (CN) are social networks consisting of scientific collaborations and collaborators [21]. In CN, the authors are represented as nodes (or vertices) and collaborations as undirected edges. CN are similar to citation networks in the scientific literature [22]. However, CN have better social and collaborative implications [23]. CN Analysis has already been studied and applied to a couple of fields but never to AIS [23–25]. Indeed, studies on co-authorship analysis have shown how visible and influential can article be [26]. Other studies have focused on examining academic research performance based on a co-authorship network of centrality and gender [27].

We use several existing methods to analyze a CN of AIS as follows:

We used the R package [28] to calculate the degree, closeness, and betweenness centrality for the binary undirected co-authorship network. In the following sections, we illustrate and discuss the 20 highest ranking authors for each of the following metrics:

**Degree** is a measure of the unique number of collaborators an author has.

**Closeness**, that is only applied to the largest (connected) component, is a measure of how authors are directly connected to a well-connected author.

**Betweenness** is a measure of a node’s influence for information flow in the network. Betweenness measures how many times a node is visited when two random nodes are connected through a path of nodes.

For more information about centrality measures and SNA, please refer to [20].

## 2.2 PageRank

PageRank [29], or eigenvector centrality, is used by the Google search engine to determine a page’s relevance or importance. Important pages receive a higher PageRank and are more likely to appear at the top of the search results. PageRank is based on backlinks. The more quality backlinks the higher google pagerank.

Liu et al [23] have applied PageRank to a co-authorship network of the Digital Science domain in order to identify prestigious authors. They transformed each unidirectional edge into a set of bi-directional, symmetrical edges.

### 2.3 AuthorRank

Liu et al [23] also define a modification of PageRank, that they call AuthorRank. PageRank assumes that when a node  $A$  connects to  $n$  other nodes, it receives a weight based on an equal fraction  $\frac{1}{n}$ , whereas AuthorRank attributes different weights for each author based on the number of their publications in common *ibid*.

Both PageRank and AuthorRank are measures of prestige that we use to identify leading authors in the domain of AIS as discussed in the following section.

We used the R package [28] to implement PageRank and AuthorRank to rank the top ranking authors and to visualize the co-authorship network using a Fruchterman Reingold Layout.

## 3 Results and Discussion

### 3.1 Publication Distribution Analysis

In order to answer the numerous doubts about a decline in the AIS field, we have measured the number of publications that are relevant to the field over time. Furthermore, we have fitted our observation using exponential functions to study the growth of publication size over time and to predict it over the years to come. We have used the coefficient of determination  $R^2$  in order to validate the fitness function and its prediction as shown in figure 1.

**Fig. 1.** Number of Publications per year 1) according to the AIS bibliography [blue], 2) according to google scholar results for “Artificial Immune Systems” [green] and 3) for all indexed Pubmed articles [red] per year. The results show a relative growth in the domain based on both AIS bibliography and Google Scholar results. The exponential fits are validated using the  $R^2$  coefficient.

Contrary to previous fears of a stagnating AIS field, we have shown that the field of AIS is ever growing by measuring the number of publications over time. Indeed, we have used exponential fitness functions in the form of  $f(x) = c.e^{(x.b)}$ , where  $c$  is a constant,  $x$  is the year index and  $b$  is the growth factor. We have compared the growth in the volume of AIS articles according to our AIS bibliography ( $b = 0.2$ ) to that of indexed Pubmed articles ( $b = 0.03$ ) between the years of 1984 and 2008<sup>1</sup> using Corlan's Medline trend (<http://dan.corlan.net/medline-trend.html>) to cement our conclusion regarding the relative expansion of the AIS domain. Furthermore, we add to our perspective the number of articles returned by Google Scholar for the query "Artificial Immune Systems" which results in a faster growing trend ( $b = 0.4$ ) as shown in green in figure 1. Dasgupta's Bibliography includes conference proceedings, as can be found in Google Scholar, whereas PubMed indexes journal articles only. However, we argue that in the fields of informatics and engineering, conference and workshop publications typically have higher impact

**Fig. 2.** The distribution of publications per authors forms a gaussian distribution around two authors.

In addition, we have analyzed the number of authors per publication that is an indication of collaboration strength. As shown in figure 2, most collaborations include two authors. Moreover, there are more 3 co-authored publications than (and almost as many 4 co-authored publications as) single authored ones. We presume that this may be as a result of the field of AIS being a very collaborative one. Indeed, a highly interdisciplinary field such as AIS invites collaborations from the fields of immunology, systems biology, artificial intelligence, machine learning, data mining...etc. Similar studies have been conducted on the field of the Digital Library Research Community [23] yielding similar results with 28.5% of papers authored by 2 authors, 23.6% by 3 authors, 19.6% by a single author and 9.4% by 4 authors.

<sup>1</sup> The years covered in the AIS Bibliography

### 3.2 Co-Authorship Network Analysis

The co-authorship network is summarized in table 1 and visualized in figure 3.

| Network Statistics     |        |
|------------------------|--------|
| Articles               | 1044   |
| Number of Vertices     | 994    |
| Number of Edges        | 1768   |
| Network Density        | 0.0036 |
| Number of Clusters     | 159    |
| Largest Component Size | 55%    |

**Table 1.** Co-Authorship network summary

The number of publications per author may be a good indicator of an author's contribution to the field however that can be biased in favor of non-collaborative authors with many published articles. The author's degree, or number of unique collaborators, can be a better measure of an author's collaborative efforts in a field. Degree centrality measures authors' connectivity with immediate neighbors or collaborators. Some authors may, however, be locally well connected but not globally with the entire network. Closeness centrality expands on degree centrality and favors authors that are connected (directly or indirectly) to as many authors in the network. Betweenness is another measure of centrality that measures how often a node is on a shortest path between any two random nodes in the network. Betweenness conveys the role of an author as an information spreader or a hub. The authors with the highest number of publications, degree, betweenness and closeness are listed in table 2. Authors with the highest degree, betweenness and closeness measures are illustrated in figure 4.

Several studies have analysed Co-authorship Network (CN) components for various scientific domains. Nascimento [24] reports the largest component in SIGMODs<sup>2</sup> CN having about 60% of all authors. Newman [25] has studied several CN with the smallest "largest component", containing 57.2% of all authors. Liu et al [23] report in the JCDL<sup>3</sup> CN the largest component of only 38% (599 authors) of all authors for the years between 1994 and 2003. The low percentage may be due to a relative immaturity of the Digital Library (DL) field. The AIS CN has the largest component of 55% (550 authors) of all authors, thus showing a relative maturity of the field. We suspect that the maturity of AIS is related to 10 years of the dedicated conference, ICARIS, since 2002 and 20 years since the beginning of AIS, i.e. twice as longer than the DL field. The largest component of 550 authors is visualized in black at the center of figure 3, whereas the remaining components alternate in various colors around it. Moreover, table 3

<sup>2</sup> SIGMOD is a Special Interest Group on Management Of Data under the Association of Machinery, ACM

<sup>3</sup> Joint Conference on Digital Library

**Fig. 3.** A visualization of the AIS co-authorship network with nodes representing authors and edges representing collaborations (with at least one co-authored article). Each component is represented in a different color. In particular, the largest component (in black) contains 55% of all authors.

| Rank | Author     | Publications | Author    | Degree | Author    | Betweenness | Author     | Closeness |
|------|------------|--------------|-----------|--------|-----------|-------------|------------|-----------|
| 1    | Timmis     | 83           | Timmis    | 50     | Timmis    | 86260       | Timmis     | 0.22405   |
| 2    | Dasgupta   | 71           | Forrest   | 35     | Dasgupta  | 35531       | R-Smith    | 0.22391   |
| 3    | Forrest    | 68           | Castro    | 29     | Forrest   | 20535       | Bentley    | 0.22390   |
| 4    | Castro     | 58           | Dasgupta  | 28     | Castro    | 18859       | Nicosia    | 0.22389   |

| 20   | Tarakanov  | 15           | Gonzalez  | 12     | Bersini   | 11119       | A-Freitas  | 0.22382   |

**Table 2.** AIS authors ranked according to their number of publications, degree (or number of unique collaborators), betweenness and closeness.

| Component Size       | 1  | 2  | 3  | 4  | 5 | 6 | 7 | 8 | 9 | 10 | 11 | 12 | 15 | <b>550</b> |
|----------------------|----|----|----|----|---|---|---|---|---|----|----|----|----|------------|
| Number of Components | 39 | 60 | 22 | 15 | 9 | 4 | 1 | 2 | 1 | 2  | 1  | 1  | 1  | <b>1</b>   |

**Table 3.** AIS Co-authorship Network component sizes and frequencies with the largest component boldened

lists the component sizes and frequencies of the AIS CN showing a significant amount of smaller components. This is suggestive of many existing AIS sub-communities, that collaborate individually but can eventually collaborate with other sub-communities .

Table 2 distinguishes Jon Timmis as a top contributor and collaborator in this field, however, we are also interested in identifying other contributors in the AIS domain like the founding fathers such as Forrest and De Castro. In table 2, we identify authors with significantly high centrality (top 20 in degree and either betweenness or closeness<sup>4</sup>) such as Nicosia, A.Freitas in the AIS CN regardless of their relatively lower number of publications (not in the top 20 in number of publications). Conversely, authors such as Neal and Stibor rank amongst the top 20 for their number of publications but do not rank as highly

<sup>4</sup> We look at the betweenness and closeness together given the minute variation in the top ranked authors according to closeness centrality shown in table 2

with the centrality measures. We assume this is due to their collaboration with a fewer selection of authors. Nevertheless, Neal and Stibor reappear in the top ranking authors according to AuthorRank in table 4 for their collaborations with few but “prestigious” authors (in terms of AuthorRank) such as Timmis, Hunt and Eckert.

PageRank and AuthorRank are measures of prestige. An author ranks highly if he or she collaborate with many authors that, in turn, have many collaborators – *ad libitum*. AuthorRank gives more weight to repeated collaborations (in a weighted network), whereas PageRank distributes weights evenly (in a boolean network). The top 20 authors according to PageRank and AuthorRank are listed in table 4.

| Rank | PageRank  | AuthorRank |
|------|-----------|------------|
| 1    | Timmis    | Timmis     |
| 2    | Forrest   | Castro     |
| 3    | Dasgupta  | Neal       |
| 4    | Perelson  | Stibor     |
| 5    | Castro    | Hunt       |
| 6    | X-Wang    | Knight     |
| 7    | D-Lee     | Eckert     |
| 8    | Zuben     | Zuben      |
| 9    | Lamont    | A-Freitas  |
| 10   | Aickelin  | Watkins    |
| 11   | J-Kim     | Andrews    |
| 12   | Coello    | Clark      |
| 13   | Tarakanov | Hart       |
| 14   | Hart      | Ayara      |
| 15   | Nicosia   | Lemos      |
| 16   | Chowdhury | Mohr       |
| 17   | Fukuda    | Secker     |
| 18   | Yang      | Owens      |
| 19   | Gonzalez  | Hone       |
| 20   | J-Zhang   | Kelsey     |

**Table 4.** Authors ranked according to the metrics of PageRank and AuthorRank.

We are equally interested in identifying contributors to the field with leading AIS theoretical models, such as Jerne, Matzinger, Perelson, Bersini, Varela, Carneiro and Greensmith, recurrent committee members of the International Conference of Artificial Immune Systems (ICARIS) such as Timmis, Forrest and Nicosia, as well as principle investigators or team leaders in AIS, such as Hart, Timmis, Von Zuben and D. Dasgupta. Many of these names appear repeatedly in table 2 of top ranking authors according to centrality measures, and in table 4 of top ranking authors according to PageRank and AuthorRank.

Finally, we are interested in understanding large network components that are disconnected from the largest component such as those led by Fukuda, Kara, Watanabe and Coello. We presume that separation is due to language and geographic barriers but we hope to have a more integrated network or more methodological explanations about this segregation in the near future. We are as well interested in understanding cluster properties of the largest component mainly led by team leaders, namely, Forrest, Timmis, Hart, Dasgupta and Tarakanov.

**Fig. 4.** Alphabetically sorted list of authors with the highest degree, betweenness and closeness

### 3.3 Conclusion and Future Directions

Several reviews have discussed advances in the field of Artificial Immune Systems but all from a qualitative perspective. Recent reviews have alluded to a stagnation in the field of AIS. In this work, we investigated these questions from a quantitative perspective. Our results have shown that the field has been growing ever since it was established for the past couple of decades. In addition, we have identified leading contributors by co-authorship network analysis based on AIS-relevant publications.

We acknowledge that the bibliography may be biased towards an engineering perspective as it is maintained by a computer scientist thus dismissing fundamental contribution from the theoretical immunology perspective. However, our method can be applied to any bibliography (structured or unstructured) in any scientific domain. Hence, we expect our analytical method not only to motivate the AIS community and encourage external scientists to entertain the challenges presented by AIS, but also to be a benchmark for scientific domain analyses.

## Extended Abstract

In nature, animals rely upon migratory behaviors in order to adapt to seasonal variations in their environment. However, the transmission of migratory behaviors within populations (either during lifetimes or throughout successive generations) is not well understood (Bauer et al., 2011). In *Artificial Life* research, *Agent Based Modeling* (ABM) is a bottom-up approach to study evolutionary conditions under which adaptive group behavior emerges. ABM is characterized by synthetic methods (understanding via building), and is becoming increasingly popular in animal behavior research (Sumida et al., 1990). Combining an *Artificial Neural Network* (ANN) and *Evolutionary Algorithm* (EA) for adapting agent behavior (Yao, 1993) has received significant research attention (Phelps and Ryan, 2001), (Lee, 2003).

ABM is an analogical system that aids ethologists in constructing novel hypotheses, and allow the investigation of emergent phenomena in experiments that could not be conducted in nature (Webb, 2009). Numerous studies in ethology have formalized mathematical models of migratory patterns in various species (Bauer et al., 2011). However, there have been few studies that examine ontological and phylogenetic conditions requisite for emergent migratory behavior. ABM is advantageous (compared to formal mathematical models of migratory behavior), since various evolutionary processes can be simulated, and variations in resultant migratory behaviors examined. For example, ABM has been used to predict the consequences of forced human migrations (Edwards, 2009), and migratory behavior between groups of Macaque monkeys (Hemelrijk, 2004).

In this research, ABM is used to investigate a hypothesis posited in ethological literature: that migratory behavior is adopted as an adaptive foraging behavior, where such behavior is either genetically or culturally determined (Huse and Giske, 1998). This study aims to investigate the evolutionary and cultural conditions that give rise to migratory behaviors and thus adaptive foraging. In cultural behavioral transmission, ontogenetic transfer occurs between agents during their lifetime. Alternatively, migratory behavior is phylogenetically transmitted through successive generations (Bauer

et al., 2011). A minimalist simulation model (distribution of four food patches and 200 agents on a grid) demonstrates the impact of ontogenetic versus phylogenetic transmission of migratory behavior and thus agent group adaptivity.

Agents use an ANN controller (figure 1, left). ANN connection weights are adapted with an EA. Agent fitness is the food amount consumed during a lifetime (200 iterations). The EA selects for effective foraging behaviors, which depends upon agents periodically migrating to where food is plentiful. Stimuli for migratory behavior take the form of cyclic *seasons* in the environment and agents signaling their movement direction to neighbors. When it is *winter* (food is scarce) in one half of the environment, it is *summer* (food is plentiful) in the other half, where each seasonal cycle (50 iterations) the winter and summer zones are switched.

Each iteration, agents receive the sensory inputs: *signal* from the closest agent, their current *fitness* and *recurrent* connections (activation value of the hidden layer in the previous iteration). Agent behavior is: *move* to an adjacent grid square, *mimic* or *mate* with a neighboring agent. The output with the highest activation is selected (figure 1, left). Each iteration, agents also emits a signal (output not depicted in figure 1), conveying the sender's current direction of movement and thus indicating migratory behavior.

Via choosing to *mimic* or *mate*, agents either imitate their neighbor's migratory behaviors or pass genetically encoded migratory behaviors onto their offspring. If an agent mimics, it copies the ANN connection weights of its closest neighbor, thus mimicking its neighbors behavior, which includes the *direction* signal sent each iteration. If an agent mates, fitness proportionate selection (Eiben and Smith, 2003) is used to select a mate from the agent population. Genotypes (floating-point value strings) encoding the ANNs are recombined using 2-point crossover (Eiben and Smith, 2003). Two child ANNs are produced and replace the parents to keep the population size constant. If an agent moves, then it moves one grid cell *north*, *south*, *east*, or *west* (figure 1, left).

Figure 1 (center and right) illustrates agent adaptation occurring over evolutionary time. Agents become effective gatherers via learning a migration behavior allowing them

Figure 1: *Left*: Each agent is a recurrent feed-forward ANN. *SI*: Sensory Input. *MO*: Motor Output. *HL*: Hidden Layer. *Center*: Average agent group fitness over 400 generations of neuro-evolution. *Right*: Average mimicry ratio over 400 generations.

to move about the environment in synchronization with the seasons (moving to where food is plentiful). Figure 1 also delineates a cyclic process in agent adaptive behavior, and the relationship between fitness and behavioral mimicry. *Mimicry ratio* indicates the average preference of an agent to mimic over another behavior. Figure 1 (center) also indicates agents periodically adapt to effective foraging behavior (indicated by fitness spikes). Fitness increases result from agents adopting migratory behaviors to adapt to the environment's seasonal variation, where such increases are enhanced by behavioral mimicking in preceding generations.

We hypothesize that subsequent periodic fitness drops, and preceding mimicry ratio decreases (figure 1, right), result from the selection and propagation of fit yet non-robust behaviors. Periodic fitness increases (figure 1, center) indicate the agents converge towards an effective gathering behavior. However, concurrently, behavioral heterogeneity is bred out of the population. Convergence results in a homogenous agent group that is unable to cope with seasonal variation in the environment. This in turn causes the periodic fitness crashes (figure 1, center), where most of the population dies off, and only those agents with robust behaviors (suited to seasonal variation) survive and are selected for.

Thus, behavioral takeover in the population (accelerated by behavioral mimicry and fitness proportionate selection) results in a largely homogenous population with low genotype and fitness diversity (Wineberg and Oppacher, 2003) and non-robust behaviors. Subsequent fitness decreases reintroduce behavioral heterogeneity (and fitness diversity) into the population and allow agents to re-adapt to the environment's seasonal variation via adopting a migratory behavior. Figure 1 (center and right) also indicates that variations in the mimicry rate impact the rate of agent adaptation and re-adaptation, as well as the duration of fitness spikes. That is, fitness increases are correlated with high mimicry ratios and fitness crashes cause behaviors containing the propensity to mimic to be periodically lost, and then rediscovered in the subsequent re-adaptation phase.

Whilst preliminary results indicate the importance of behavioral mimicry and genetic transmission of migratory be-

haviors to a population's overall adaptivity (supporting ethological research), their contribution to adaptive behavior is subject to ongoing research. Current investigation is of conditions under which cultural versus genetic transmission of migratory behaviors prevail, and the impact of lifetime duration on cultural and genetic transmission of behaviors.

## Abstract

Migration is a fundamental trait in humans and animals. Recent studies investigated the effect of migration on the evolution of cooperation, showing that contingent migration favors cooperation in spatial structures. In those studies, only local migration to immediate neighbor sites was considered, while long-range migration has not been considered yet, partly because the long-range migration has been generally regarded as harmful for cooperation as it would bring the population to a well-mixed state that favors defection. Here, we studied the effects of adaptive long-range migration on the evolution of cooperation through agent-based simulations of a spatial Prisoner's Dilemma game in which individuals can jump to a farther site if they are surrounded by more defectors. Our results show that adaptive long-range migration strongly promotes cooperation, especially under conditions where the temptation to defect is considerably high. These findings demonstrate the significance of adaptive long-range migration, a naturally observed migration style in human and animal behaviors, for the evolution of cooperation.

Migration is a fundamental trait in humans and animals. Recent studies investigated the effect of migration on the evolution of cooperation, showing that contingent migration favors cooperation in spatial structures. One limitation in the earlier contingent migration studies is that migration was commonly assumed to be limited only to immediate neighbor sites of each individual. To our knowledge of the relevant literature, no existing work addressed the effect of *adaptive long-distance migration* on the evolution of cooperation, partly because the long-range migration has been generally regarded as harmful for cooperation as it would bring the population to a well-mixed state that favors defection. We believe, however, that adaptive long-range migration may be beneficial for cooperators because they may be able to escape from defector-dominated areas at once and potentially land in a community of other cooperators.

Here, we studied the effects of adaptive long-range migration on the evolution of cooperation. For this, we developed an agent-based model in which individuals play the Prisoner's Dilemma (PD) game with local nearest neighbors on a regular spatial grid and may migrate to another site if the local situation is unfavorable. The key unique contribu-

tion of our work is to use an adaptive distance for long-range migration based on the number of defectors in the individual's vicinity, so that the possible distance of the adaptive migration is longer with more defectors in the area nearby. The square lattice is composed of  $L \times L$  sites with periodic boundary conditions. Each site is either empty or occupied by one individual. Empty sites represent spatial regions that individuals can migrate to. Initially, individuals are randomly distributed over the square lattice. One half of them are set to be cooperators while the other defectors. Their population density is given by  $\rho$ . The population density remains constant throughout a simulation run, since individuals will never die or be born.

Individuals are updated asynchronously in a randomized sequential order. The algorithm for updating an individual consists of the following three phases:

1. *Migration.* First, to decide the site to move into, the individual counts the number of defectors,  $n_D$ , within its  $n$  neighbors. Using  $n_D$ , the maximum migration distance is calculated as  $d_{\max} = \text{round}((n_D/n)^\alpha d)$ , where  $\alpha$  and  $d$  are experimental parameters.  $\text{round}(\dots)$  is used here because the space is discrete. Then the individual moves to a randomly selected empty site within a  $(2d_{\max} + 1)$ -by- $(2d_{\max} + 1)$  square region around its original location.
2. *Game play.* After the migration, the individual plays the PD game with other individuals within its  $n$  nearest neighbor sites and accumulates the payoffs resulting from the games. In each game, two individuals decide whether to cooperate or defect simultaneously based on their current strategies. They both obtain payoff  $R$  for mutual cooperation while  $P$  for mutual defection. If one selects cooperation while the other does defection, the former gets the sucker's payoff  $S$  while the latter gets the highest payoff  $T$ , the temptation to defect. The relationship of the four payoffs is usually  $T > R > P > S$  in PD games. Following the parameter settings used in the earlier studies, we used  $P = 0$ ,  $R = 1$ , and  $S = 0$ , while  $T > 1$ , the temptation to defect, was varied as an experimental parameter.

3. *Strategy updating.* Once all the games are over, the individual imitates the strategy of the other individual that achieved the highest total payoff among its neighbors.

When all individuals finish conducting the three phases above, it constitutes one time step of the simulation, which we refer to as a “generation.”

The parameter setting used for the experiments is as follows:  $L = 50$ ,  $\rho = 0.3$ ,  $n = 8$  (Moore neighborhood). We systematically varied values of  $\alpha$  and  $d$  to represent the following six different types of migration:

- $\alpha = 0$ ;  $d = 1$ : random short-range migration (RSM)
- $\alpha = 0$ ;  $d = 8$  ( $> 1$ ): random long-range migration (RLM)
- $\alpha = 0$ ;  $d = 24$  ( $\sim L/2$ ): random global migration (RGM; an extreme case of RLM)
- $\alpha = 1/3, 1$ , or  $3$ ;  $d = 1$ : adaptive short-range migration (ASM)
- $\alpha = 1/3, 1$ , or  $3$ ;  $d = 8$  ( $> 1$ ): adaptive long-range migration (ALM)
- $\alpha = 1/3, 1$ , or  $3$ ;  $d = 24$  ( $\sim L/2$ ): adaptive global migration (AGM; an extreme case of ALM)

The main experimental measurement obtained from each simulation run is the equilibrium fraction of cooperators,  $\bar{f}_c$ , after a certain time period elapses.

By conducting evolutionary simulations, we found that ASM, ALM, and AGM strongly promotes cooperation compared to RSM, RLM, and RGM, especially under conditions where the temptation to defect is considerably high. Figure 1 shows  $\bar{f}_c$  as a function of  $T$ . For the low values of  $T$ , all migration types sustained a high level of cooperation (except for  $\alpha = 3$  that made migration rather infrequent). In highly tempting conditions ( $T > 3$ ), cooperators were easily exploited by defectors in RSM, RLM, and RGM. In ASM, cooperators were allowed to move in response to the presence of defectors, but they often remained near the defectors and were exploited by them. In ALM and AGM, in contrast, cooperators were able to secure a certain distance from defectors after the adaptive migration, and thus cooperation was promoted even under highly tempting conditions. Even complete segregation between cooperators and defectors was possible in ALM (for  $\alpha = 1/3$ ) and AGM (for  $\alpha = 1/3, 1$ ) (Fig. 2).

In conclusion, we investigated the effect of adaptive long-range migration on the evolution of cooperation in a spatial population model. Compared to earlier studies that assumed only short-range migration, we found that adaptive long-range migration strongly enhanced the evolution and maintenance of cooperative behavior, especially under high tempting conditions where other forms of migration did not.

Figure 1: Equilibrium fraction of cooperators ( $\bar{f}_c$ ) as a function of temptation to defect ( $T$ ).  $\rho = 0.3$ .

Figure 2: Typical snapshots of simulations after 10,000 generations. Blue and red dots represent cooperators and defectors, respectively. Cooperators dominated in the population in ALM ( $\alpha = 1/3$ ) and AGM ( $\alpha = 1/3, 1$ ). In those cases, cooperators successfully maintained a certain distance with defectors.  $T = 3.5$  and  $\rho = 0.3$ .

An extended version of this manuscript will soon be posted to arXiv.org.

# Testing Biological Models for Non-linear Sensitivity with a Programmability Test

Hector Zenil, Gordon Ball and Jesper Tegnér

Unit of Computational Medicine

Karolinska Institute

Centre for Molecular Medicine, Solna, Stockholm, Sweden.

{hector.zenil,gordon.ball,jesper.tegner}@ki.se

## 1 Introduction

We address the question of what kind of test could be implemented to establish whether an artificial system is living or not with a computability and programmability test as advanced in [2]. We claim that necessary conditions for life are non-linear behavioural variability and sensitivity to external stimuli.

We advance an algorithmic information concept of programmability as a combination of behavioural change and external control similar to the one presented in [1] in the context of self-assembly and non-DNA spatial computation. We look into evaluating, classifying and discriminating biological models from the BioModels Database (<http://www.ebi.ac.uk/biomodels-main/>), a centralized database of curated quantitative models of biochemical interest whose dynamical space, time-evolution and model's reaction to their “environment” (sensitivity) is studied, leading to questions such as the robustness and param-

eter orthogonality.

Similarity metrics and information distances are applied and results are presented in the direction of characterisations of the behaviour of physical and natural systems, allowing the classification of qualitative properties and the assessment of simulation results in terms of algorithmic information content with special focus on transitions, clustering, variability and space parameter discovery and behavioural mapping.

The testing approach based on a system capability to react to external stimuli and transfer information as reflected in the proposed measures of programmability indicate the susceptibility of a system to be (efficiently) programmed where we can ask questions such as whether programmability differences originate from either (a) a structural difference in the modelling equations, or (b) differences in how much parameters are allowed to vary, and thereby having a greater/smaller flexibility to respond to external stimuli. Model understanding may be hindered by the assumed dataset and the estimated parameters on which models are often heavily dependent. The approach promises to provide some further insight on different types of biological models.

# SimSoup: Molecules Designed for Switchable Autocatalytic Memory

Chris Gordon-Smith<sup>1</sup>

<sup>1</sup>SimSoup  
c.gordonsmith@gmail.com

## Abstract

A memory system based on an artificial chemistry is presented. This is relevant for metabolism based Origin of Life theories, and in the field of biological and chemical computing. Each memory unit can be switched between three alternative active states. A unit maintains itself in a particular state using an autocatalytic reaction process. Switching between states occurs when an external stimulus triggers the autocatalytic process for the new state, along with an associated process that inhibits autocatalytic activity for the old state. Artificial molecular species with structures designed to support the autocatalytic and inhibiting processes are presented. The SimSoup artificial chemistry simulator is used to show that the structures do indeed produce the memory system behaviour. With the advent of engineering at the molecular level, it may be possible to transfer the concepts from an *in silico* environment to a chemical environment.

## Introduction

### Background And Motivation

**Inheritance at the Origin of Life.** Contemporary organisms and viruses use DNA or RNA template molecules to provide the memory needed for inheritance and evolution. Origin of Life research suggests that template molecules and the associated enzymes needed for their accurate replication are too complex to be plausible in a prebiotic environment. Some Origin of Life theories envisage *metabolism based* inheritance in which protocells or lipid enclosed droplets without template molecules reproduced by growth and division. Variations in the metabolisms of different individuals would have led to differences in fitness that would drive evolution. For this to be workable, successful variations in metabolism would have to be ‘remembered’ and passed on to offspring.

The SimSoup project is investigating memory in chemical networks that could have supported metabolism based inheritance in early organisms.

**Biological and Chemical Computing.** A key challenge for the newer field of biological and chemical computing is the development of memory systems using components that can be readily constructed and manipulated. Such systems may be used for various purposes, including the provision of

an inheritance mechanism for the evolution of artificial systems. The simple memory mechanisms being investigated by SimSoup are also relevant in this field.

## Conceptual Background

The SimSoup project takes inspiration from:

- Metabolism based Origin of Life theories including those of Aleksandr Oparin (Oparin, 1957), Stuart Kauffman (Kauffman, 1993), Freeman Dyson (Dyson, 1999), and the Lipid World theory and GARD model of Doron Lancet’s group (Segré et al., 1998, 2001a,b)
- Günter Wächtershäuser’s chemo-autotrophic Iron-Sulphur World (Wächtershäuser, 2006)
- Walter Fontana’s Algorithmic Chemistry (Fontana, 1992)
- Graham Cairns-Smith’s clay crystal and genetic takeover theory (Cairns-Smith, 1982)
- Tibor Gánti’s principles of life and chemoton theory (Gánti, 2003)
- Network theory, particularly the work of Sanjay Jain and Sandeep Krishna (Krishna, 2003)
- The Chemical Organisation Theory of Peter Dittrich and Pietro Speroni di Fenizio (Dittrich and di Fenizio, 2007)
- Linus Pauling’s chemical bond theory (Pauling, 1960).

## The SimSoup Artificial Chemistry Model

The main features of the model are outlined below. A detailed description is available elsewhere (Gordon-Smith, 2013). The program code is also available (SimSoup, 2013).

SimSoup *Molecules* are two dimensional rigid structures built from *Atoms* bonded together such that they occupy fixed positions on a square ‘Board’ (similar to a chess board). Each square contains at most one Atom. Bond angles are always either 90° or 180°, and bond lengths are all equal. Atoms bond together in a way broadly consistent with valence bond theory. Each distinct molecular structure (or species) is a *Molecule Type*.

Molecules can join or split to form Molecules of different types. Joining must respect the ‘one Atom per square’ rule, and can take place with the Molecules in any of their eight possible relative orientations. Splitting occurs by breaking the weakest set of bonds that hold the Molecule into a single unit. When two Molecules join (eg  $A + B \rightarrow C$ ), a *Construction Interaction* takes place. A splitting interaction (eg  $D \rightarrow E + F$ ) is called a *Fission Interaction*.

Bond strengths are usually fixed according to the types of Atom at each end of the bond. However, some bonds are *Perturbable*; they can be weakened or strengthened by nearby Atoms that do not themselves participate in the bond.

Construction and Fission Interactions take place in a well-mixed *Reactor*. This is the physical environment in which the Molecules exist. Interaction rates are determined by rate constants that are calculated using parameters analogous to the Arrhenius parameters used by chemists. Fissions typically proceed more quickly for Molecule Types with weak bonds. The rates of Constructions are proportional to the product of the concentrations of the reactants.

### Previous Work: A Non-Switchable Memory Bank

A previous work (Gordon-Smith, 2011), described an artificial chemistry providing a ‘memory bank’. The motivation was to provide a proof of concept demonstrating that a chemical network could have a large number of alternative states, as would be needed for metabolism based inheritance.

Each memory unit in the previous work is an *Autocatalytic Sub-Network* within the overall network, and has two states: active and inactive. Interactions occurring in the active state produce Molecules needed for further activity. Each unit corresponds to a particular monomer Molecule Type. Units are arranged in series in the network, and the shapes of their Molecule Types depend on series and position in series.

The presence or absence of monomers of particular types in the Reactor corresponds to stored information. Memory capacity depends on the number of monomer series, and on the number of monomer types in each series.

This previous memory bank has the drawback that the memory units are not easily switchable; once a unit has been activated it cannot be readily de-activated. It can be argued that such switchability may not be essential in some Origin of Life contexts<sup>1</sup>. However, it would be required in many chemical computing scenarios.

### A Switchable Memory Unit

This section presents an *in silico* chemical memory unit that can be readily switched between states. Multiple memory units can co-exist within the same physical environment (Reactor) without interfering with one another; this is due to specific features of the molecular structures.

<sup>1</sup>Although it may affect capacity for co-evolution.

### Concept For Switchability: Rock-Paper-Scissors

The design for switchable memory units is based on the game ‘Rock-Paper-Scissors’. The ability of a unit to ‘remember’ is due to the operation of its three Autocatalytic Sub-Networks. In order to make the memory unit switchable, a mechanism is introduced that enables activity in one Autocatalytic Sub-Network to cause activity in another to be inhibited.

Figure 1: Rock-Paper-Scissors concept for switchable memory units

The overall concept is illustrated in Figure 1. The diagram as a whole represents a switchable memory unit with three active states.<sup>2</sup> Each circle corresponds to an Autocatalytic Sub-Network maintaining one of the states. The ‘loopback’ arrows denote the (autocatalytic) positive feedback mechanisms by which they maintain themselves. The straight arrows terminating at each circle denote external stimuli that can activate the Autocatalytic Sub-Networks. The lines between circles terminated with ‘I’ symbols signify that Molecules produced by autocatalytic activity maintaining one state can inhibit activity for another state. For example, the ‘Scissors’ Autocatalytic Sub-Network inhibits the Paper Autocatalytic Sub-Network.

Except during state transitions, only one state can remain active during any period; if two are active simultaneously then one inhibits and ‘kills’ the other. If all three were active, then all three would also be inhibited, leading to an unstable state with no clear overall ‘winner’.

In order for the memory unit to be switched, an external stimulus must be provided to activate the new state. For example, if Rock is currently active, then switching occurs when an external stimulus is provided to activate the Paper state. The system then goes through a transition in which the Rock Autocatalytic Sub-Network is inhibited by a process using Molecules produced by the growing autocatalytic activity for the Paper state. The Paper state itself is *subject*

<sup>2</sup>In the inactive or ‘dead’ state, none of the three Autocatalytic Sub-Networks would be active.

to no such inhibiting constraint. If the unit is to be switched to Scissors, then two separate switching actions must take place, first to Paper and then to Scissors.<sup>3</sup>

### Overview Of Memory Unit Design

Figure 2 illustrates the design for a memory unit. It shows both the structure of the (artificial) chemical network, and a ‘thumbnail’ structure diagram for each Molecule Type involved in maintaining and inhibiting the unit’s ‘Rock’ state. The arcs between lines joining Molecule Types identify Constructions and Fissions. Specific details of the molecular structures and bonds, and the way they support the operation of the memory unit are given later, along with naming conventions for Molecule Types.

Each co-existing memory unit has its own set of characteristic ‘Rock-Paper-Scissors’ Molecule Types and states. For example, memory unit  $n$  has possible active states,  $\text{Rock}_n$ ,  $\text{Paper}_n$ , and  $\text{Scissors}_n$ , and uses Molecule Types such as  $R_n$  and  $R_{n\text{pre}}$ . Each memory unit state has an Autocatalytic Sub-Network, and an *Inhibiting Sub-Network* for the inhibition mechanism.

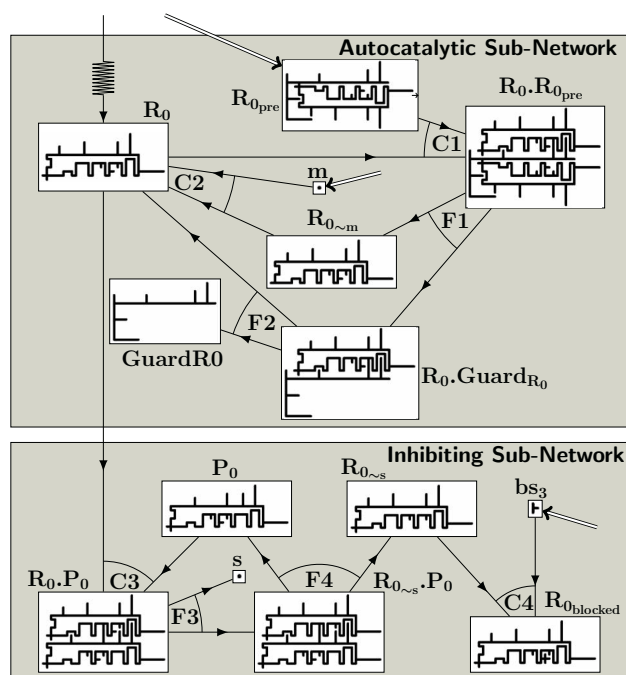

Figure 2: Overview of Network and Molecular Structures for the ‘Rock<sub>0</sub>’ State. The top section shows Molecule Types and Interaction Types for the Rock<sub>0</sub> Autocatalytic Sub-Network. The lower section shows the Inhibiting Sub-Network for Rock<sub>0</sub>. The zig-zag arrow indicates an external stimulus. Double arrows indicate a constant supply. Labelled arcs indicate Constructions and Fissions.

<sup>3</sup>The need for two stage switching is a drawback, but a consequence of the simple design in which the same input is used both for activating one sub-network and inhibiting another.

**The Autocatalytic Sub-Network.** The zig-zag arrow terminating at  $R_0$  indicates that an external stimulus consisting of a few  $R_0$  Molecules can be provided to the memory unit. The double arrows terminating at  $R_{0\text{pre}}$  and  $m$  (Metal) indicate that a constant supply of each is provided.

The autocatalytic reaction process begins when  $R_{0\text{pre}}$  and  $R_0$  combine under Construction C1 to form  $R_0.R_{0\text{pre}}$ . Each  $R_0.R_{0\text{pre}}$  Molecule then breaks up in two successive Fissions, F1 and F2. F1 produces one Molecule of  $R_{0\sim m}$  and one of  $R_0.\text{Guard}_{R_0}$ . The  $R_{0\sim m}$  Molecule goes on to combine with an ‘m’ Atom (Metal) in Construction C2 to return an  $R_0$  Molecule. F2 splits the  $R_0.\text{Guard}_{R_0}$  Molecule into one Molecule of  $\text{Guard}_{R_0}$ , and a second (excess)  $R_0$  Molecule. The overall reaction process is:

The process can only start if an initial input of  $R_0$  is provided as a catalyst. Once started, the process produces an excess of  $R_0$ , and no further external input of  $R_0$  is needed.

**The Inhibiting Sub-Network.** The Inhibiting Sub-Network impedes activity of the Autocatalytic Sub-Network by converting  $R_0$  Molecules to  $R_{0\text{blocked}}$  Molecules that cannot participate in the autocatalytic reaction process. The conversion starts with Construction C3, which produces  $R_0.P_0$  from  $R_0$  and  $P_0$ . Each  $R_0.P_0$  Molecule then splits (Fission F3) to produce an Atom of  $s$  (Stoppite) and an  $R_{0\sim s}.P_0$  Molecule. Each  $R_{0\sim s}.P_0$  Molecule splits (Fission F4) to produce a Molecule of  $R_{0\sim s}$  and a Molecule of  $P_0$ , returning the one required for Construction C3. Finally, the  $R_{0\text{blocked}}$  Molecule is produced by combining the  $R_{0\sim s}$  Molecule with a  $bs_3$  Molecule (Construction C4).

The overall reaction process for the Inhibiting Sub-Network is:

The process can only proceed in the presence of  $P_0$  as a catalyst. The Autocatalytic Sub-Network for the Paper<sub>0</sub> state produces  $P_0$ , and this is the basis by which the Paper<sub>0</sub> inhibits the Rock<sub>0</sub> state.

### Molecular Structures and Bonds

This section details the molecular structures used by the memory unit, and the way they support its operation. The structures are constructed from (artificial) Atoms that bond in particular ways, and so the Atom Types and Bond Types are described first.

#### Atom Types

The memory unit uses Atom Types with properties designed to support the Interaction Types that are needed for its operation. Table 1 shows these Atom Types. The ‘Bonds’ col-

<sup>4</sup> $\text{Guard}_{R_0}$  produces further ‘waste’ products (not shown).

um indicates the number of bonds that each Atom Type can form. All the Atom Types have mass 10.

| Name/Symbol    | Bonds | Usage / Capability                                                        |
|----------------|-------|---------------------------------------------------------------------------|
| Assemblite (●) | 2     | Used to build framework of molecular structures                           |
| Blockite (b)   | 4     | Used to build bs <sub>3</sub> 'Blocker'                                   |
| Hookite (h)    | 4     | Used to provide a 'hook' bonding site                                     |
| Junctium (j)   | 3     | Used to provide a 3 way junction in a structure                           |
| Loosium-1 (w)  | 2     | Provides a weak (loose) bonding site for Loosium-2                        |
| Loosium-2 (x)  | 2     | Provides a weak (loose) bonding site for Loosium-1                        |
| Metal (m)      | 1     | Can perturb nearby Perturbium bonds, even though not bonded to Perturbium |
| Perturbium (p) | 3     | Produces bonds that can be weakened or strengthened by nearby Metal atoms |
| Stoppite (s)   | 1     | Stops further growth of the Molecule at a site                            |

Table 1: Atom Types used for the switchable memory units

## Bond Types

Table 2 shows the Bond Types that can exist between the various Atom Types. The meanings of the cell entries are as follows:

- Blank: Atom of these types do not bond
- x: Atoms bond with Enthalpy (strength) 100
- w: Atoms bond weakly, with Enthalpy 10
- p: Perturbable Bond

|   | a | h | j | b | m | p | s | w | x |
|---|---|---|---|---|---|---|---|---|---|
| a | x |   |   |   |   |   |   |   |   |
| h | x |   |   |   |   |   |   |   |   |
| j | x | x | x |   |   |   |   |   |   |
| b |   |   |   |   |   |   |   |   |   |
| m | x | x | x |   |   |   |   |   |   |
| p | x | p | x | x |   |   |   |   |   |
| s | x | x | x | x |   | p | x |   |   |
| w | x |   | x |   |   |   |   |   |   |
| x | x |   | x |   |   |   |   | w |   |

Table 2: Bond Types: Each cell shows the characteristics of a bond between a top row Atom and a left column Atom.

A *Perturbable Bond* is one whose strength can be affected by the presence of a nearby Atom of a specific type, even though that Atom is not bonded to either of the Atoms participating in the bond. For the work described in this paper, the normal Enthalpy of the Perturbable Bonds shown in the table is 100, but reduces to 5 in the presence of a nearby Metal Atom, making the bond more likely to break quickly.

## Molecule Types

This section shows details of the Molecule Types for the memory unit, and describes the way they support its operation. Conventions for naming Molecule Types are described where they are first used.

**Core Molecule Types: R<sub>n</sub>, P<sub>n</sub>, S<sub>n</sub>.** Figure 3 shows the *Core Molecule Types* for the three Autocatalytic Sub-Networks of the n=0 memory unit. R<sub>0</sub> is produced by the Rock<sub>0</sub> Autocatalytic Sub-Network. Similarly P<sub>0</sub> and S<sub>0</sub> are produced by the Paper<sub>0</sub> and Scissors<sub>0</sub> Autocatalytic Sub-Networks respectively.

Figure 3: R<sub>0</sub> (top), P<sub>0</sub> (centre) and S<sub>0</sub> (lower): The Core Molecule Types for the Rock<sub>0</sub>, Paper<sub>0</sub> and Scissors<sub>0</sub> Autocatalytic Sub-Networks.

The following features can be noted:

- Each Molecule Type has various recesses and protuberances. These are positioned to prevent Constructions that would produce Molecule Types that interfere with the operation of the memory unit
- S<sub>0</sub> is one unit wider than P<sub>0</sub>, which is one unit wider than R<sub>0</sub>. This is also to prevent the production of interfering Molecule Types
- The three central recesses along the bottom of each of R<sub>0</sub>, P<sub>0</sub> and S<sub>0</sub> are key to the mechanisms for both autocatalysis and inhibition. The recess that includes both a Loosium-1 (w) Atom and a Stoppite (s) Atom is called the

**Owner Recess.** The recess that includes just a Loosium-1 (w) Atom is called the *Successor Recess*, and the ‘empty’ recess is called the *Predecessor Recess*

- The recesses are arranged cyclically, so that the Successor Recess for one Molecule Type lines up with the Owner Recess for the Molecule Type that ‘beats’ (or succeeds) it
- Above each Owner Recess there is a protuberance (the *Owner Protuberance*) that terminates with a Loosium-2 Atom. Above each Predecessor Recess there is a *Predecessor Protuberance* that terminates with a Metal Atom.

The roles of these protuberances and recesses in the operation of the memory unit are described later in this section.

Figure 4:  $R_1$ , the Core Molecule Type for  $Rock_1$ .

Figure 4 shows  $R_1$ , the Core Molecule Type for the  $Rock_1$  Autocatalytic Sub-Network. It is identical to  $R_0$ , except that there is an additional space to the right of the Owner Recess.  $P_1$  and  $S_1$  have similar additional space by comparison with their  $n=0$  counterparts. Core Molecule Types for larger  $n$  values have correspondingly larger spaces. The spacing ensures that corresponding Molecules (eg  $R_0$ ,  $R_1$ ) for different co-existing memory units do not interfere.

**‘Missing Atom’ Variants of Core Molecules.** Variants of the Core Molecule Types with a ‘missing’ Metal or Stop-pite Atoms occur in the Autocatalytic and Inhibiting Sub-Networks. If the Stop-pite Atom in the Owner Recess of the  $R_0$  Molecule shown at the top of Figure 3 is removed, the result is called  $R_{0\sim s}$ . Similarly, if the Metal Atom at the bottom left of the Molecule is removed, the result is  $R_{0\sim m}$ .

**Core Molecule Type Precursors and Guards.** The Autocatalytic Sub-Network for a memory unit is provided with a constant supply of *Precursors* for its Core Molecule Types.

Figure 5 shows  $R_{0\text{pre}}$ , the Precursor for  $R_0$ . This consists of  $R_{0\sim m}$  ( $R_0$  less a Metal Atom) with an adjoined *Guard*. The Guard covers the Owner, Successor and Predecessor Recesses for the Core Molecule Type, making them inaccessible to protuberances. Figure 6 shows  $\text{Guard}_{R_0}$ , the Guard for  $R_0$ .

**Role Of The Precursor.** A type  $n$  memory unit is provided with a supply of  $R_{n\text{pre}}$ ,  $P_{n\text{pre}}$  and  $S_{n\text{pre}}$ , the Precursors

Figure 5:  $R_{0\text{pre}}$ , the Precursor for  $R_0$ .

Figure 6:  $\text{Guard}_{R_0}$ , the Guard for  $R_0$ .

for its Core Molecule Types  $R_0$ ,  $P_0$  and  $S_0$ . The Precursor can be split as described shortly by the Autocatalytic Sub-Network to release a Core Molecule. The steady supply of Precursor Molecules therefore provides the ‘food’ that enables a memory unit to maintain its active state.

**Role Of The Guard.** The Guard part of a Precursor Molecule Type has two roles:

- It has a Protuberance terminated with a Loosium-2 (x) Atom that bonds weakly to the Loosium-1 (w) Atom in the corresponding Core Molecule Type to form a Precursor Splitter Complex
- It prevents Precursors from combining with successor Core Molecules to produce Precursor.Core Complexes instead of Core.Core Complexes that are essential for the Inhibiting Sub-Network.

**The Precursor Splitter Complex.** A Core Molecule Type can join with its Precursor to produce a *Precursor Splitter Complex*. Figure 7 shows the Precursor Splitter Complex,  $R_0.R_{0\text{pre}}$ , for the  $Rock_0$  Autocatalytic Sub-Network.

The two Molecules join at the Loosium-1 to Loosium-2 (w-x) bond in the Core Molecule’s Owner Recess (see Construction C1 in Figure 2). The Metal Atom at the bottom left of the Core Molecule is placed just above (but not bonded to) the Perturbium-Hookite bond at the top left of the Precursor.

Figure 7:  $R_0.R_{0_{pre}}$ : The Precursor Splitter Complex for the  $Rock_0$  Autocatalytic Sub-Network

This weakens the bond, which soon splits (Fission F1) releasing a ‘missing Metal’ variant of the Core Molecule and a Reverse Guard Complex (see next section).

The ‘missing Metal’ Core variant combines with freely available Metal to form a Core Molecule. This replaces the Core Molecule that combined with the Precursor.

**The Reverse Guard Complex.** When a Precursor Splitter Complex splits, one of the products is a *Reverse Guard Complex*. This is a Core Molecule with a Guard in a ‘reverse’ configuration. Figure 8 shows the Reverse Guard Complex,  $R_0.Guard_{R_0}$ , for the  $Rock_0$  Autocatalytic Sub-Network.

Figure 8:  $R_0.Guard_{R_0}$ , the Reverse Guard Complex for the  $Rock_0$  Autocatalytic Sub-Network

The Reverse Guard Complex is held together by the Loosium-1 to Loosium-2 (w-x) bond that was formed when the Core Molecule joined with a Precursor in Construction C1. This is a weak bond (see Table 2), and soon breaks (Fission F2), releasing a Core Molecule and an (un-needed)

Guard. The Core Molecule released here is the one that previously combined with the Precursor. A Core Molecule was also produced by Fission F1, and so there is an excess.

**The Core.Core Complex.** Two Core Molecule Types for different states of the same memory unit can join to form a *Core.Core Complex* that plays a key role in the Inhibiting Sub-Network. Figure 9 shows the  $R_0.P_0$  Core.Core Complex.

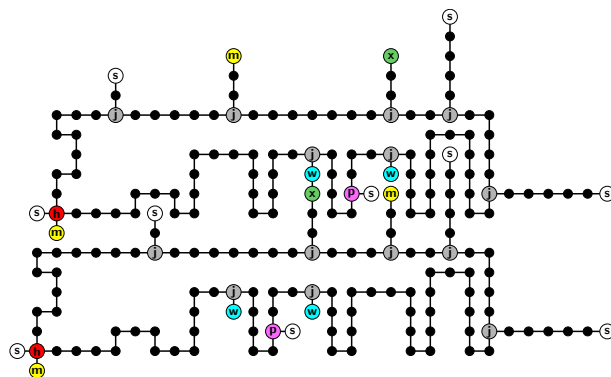

Figure 9:  $R_0.P_0$ : The Core.Core Complex for the  $Rock_0$  Inhibiting Sub-Network

The two Core Molecules are joined at the weak Loosium-1 to Loosium-2 (w-x) bond in the top Molecule’s Successor Recess, and will soon break apart again (Fission F4). However, while the complex persists, a Metal Atom from the lower (Successor) Molecule is held next to the Perturbium to Stoppite bond in the top Molecule’s Owner Recess. This bond is weakened, and the Stoppite Atom soon splits off (Fission F3). This makes available a bonding site that will be used to block autocatalysis.

**Blocked Core Molecule Types and bs3 Blockers.** The Inhibiting Sub-Network converts Core Molecules to *Blocked Core Molecules* that cannot participate in the autocatalytic reaction process.

Figure 10:  $R_{0_{blocked}}$ : the Blocked Core Molecule for the  $Rock_0$  Inhibiting Sub-Network

The blocking is achieved by incorporating a small *Blocker* Molecule,  $bs_3$ , into the Core Molecule’s Owner Recess.

This is done by removing a Stoppate Atom from a Core Molecule to produce a 'missing Stoppate' variant (Fissions F3 and F4), and attaching a freely available Blocker at the bonding site that this creates (Construction C4).

Figure 10 shows  $R_{0\text{blocked}}$ , the Blocked Core Molecule Type for  $R_0$ . The small  $bs_3$  Blocker can be seen in the Owner Recess.

## Results

Figure 11 shows the operation of a 9-state memory system comprising two 3-state memory units co-existing in the same Reactor. The scenario was as follows:

- Atom Types and Bond Types as described earlier
- A constant supply of Precursors for the  $n = 0$  memory unit ( $R_{0\text{pre}}$ ,  $P_{0\text{pre}}$  and  $S_{0\text{pre}}$ ) is provided, 400 of each every 10 timesteps
- A similar supply of  $n = 1$  Precursors is setup
- A constant supply of Metal Atoms and  $bs_3$  Blockers is setup, 2000 of each every 10 timesteps
- A small stimulus of 7  $R_0$  Molecules is input at time 10000, and at subsequent intervals of 60,000 timesteps. Similar series of stimuli are setup for  $P_0$  and  $S_0$ , starting at times 30,000 and 50,000 respectively
- Stimuli are setup for the  $n = 1$  Core Molecules at times 10,000, 70,000 and 130,000
- Each Molecule has a removal probability at each timestep of 0.005.

The top plot shows that following the  $R_0$  stimulus at time 10,000, the number of  $R_0$  Molecules in the Reactor rises from zero to about 850, and stays at that level. This is due to the operation of the  $Rock_0$  Autocatalytic Sub-Network. At time 30,000 the  $P_0$  stimulus is added. The number of  $P_0$  Molecules rises to about 850 due to the operation of the  $Paper_0$  Autocatalytic Sub-Network, and the number of  $R_0$  Molecules falls to zero due to the operation of the  $Rock_0$  Inhibiting Sub-Network. The rest of the plot shows repeated cyclic switching between states of the  $n = 0$  unit.<sup>5</sup>

The middle plot shows the numbers of Core.Core Complex Molecules. These are key to the operation of the Inhibiting Sub-Network during the transition from one state of the memory unit to another. As the plot shows, they are present only during these transitional periods.

The lower plot shows the numbers of Core Molecules for the co-existing  $n = 1$  memory unit. The top and lower plots together show that the system as a whole has 9 states, corresponding to the number of possible states for two independently switchable 3-state units.

<sup>5</sup>The small excess of  $P_0$  at time 100,000 is as yet unexplained.

Figure 11: Operation of two co-existing 3 state memory units. Top: The  $n = 0$  unit cycling through its three states. Middle: Numbers of Core.Core Complexes present during switching of the  $n = 0$  unit. Bottom: The  $n = 1$  unit cycling through its three states.

## Conclusions

1. It has been demonstrated that it is possible to produce a switchable memory unit using (artificial) Molecules with structures specifically designed to produce a reaction network with Autocatalytic and Inhibiting Sub-Networks
2. It is possible to combine multiple memory units in the same (well mixed) chemical environment in such a way that they do not interfere with each other's operation. In the results presented here, two 3-state units were combined to produce a memory system with 9 states
3. The design of the Molecules is such that further memory units with higher  $n$  values can be produced by new Core Molecule Types with additional spaces to the right of the Owner Recess. The number of states for a system including  $m$  memory units is  $3^m$ , and the number

of Core Molecule Types needed is  $3m$ . A memory system with 30 Core Molecule Types could therefore support  $3^{10} = 59049$  states. The number of states for a system with 60 Core Molecule Types would be almost 3.5 million

4. From an Origin Of Life perspective, a population of protocells can be envisaged, each containing a memory system in a particular state. The memory system would influence other aspects of a larger reaction network affecting behaviour, such that it could support an evolutionary process in which fitter protocells were selected.

It can be argued that an inheritance mechanism supporting 3.5 million alternative ‘phenotypes’ provides sufficient scope for such an evolutionary process to get a foothold. This would require a protocell to have a foodset including 60 Core Precursor Molecule Types. This requirement may not be as stringent as appears at first sight; the Core Molecule Types and the Precursors all follow the same basic pattern. It can be envisaged that they could be produced by a systematic process with scope for random variations within the framework of that pattern

5. From the perspective of chemical and biological computing systems, it may be possible, with the advent of engineering at the molecular level, to use the concepts described here as the basis of a similar artificial evolutionary mechanism, or as memory for different applications.
6. The molecular structures shown in this paper are just one way of implementing the memory units. It is likely that there are many alternatives with totally different structures. Molecular structure design could take account of considerations regarding what can be easily engineered
7. There is a trade-off between the chemical complexity involved in a larger number of Core Molecule Types required for co-existing memory units vs physically separate memory units but fewer Core Molecule Types. For droplet (or ‘protocell’) based artificial evolution, the former is likely to be preferred, as it does not require physical separation of different memory units within the droplet.

## Prospects

The author would like to hear from anyone interested in transferring the concepts described here from an *in silico* environment to a chemical environment.

# The emergence of life and evolution: Towards a categorical approach

Roland Cazalis

SPS/URBV, University of Namur, Belgium  
roland.cazalis@fundp.ac.be

## Abstract

Among the list of proposed questions in “Open Problems in Artificial Life” (Bedau et al. 2000) the first, “how does life arise from the nonliving?” is certainly one of the most difficult to answer. The first and main challenge in the understanding of the way that life emerged from the nonliving comes from our lack of knowledge of the living organism and paradoxically, the limitations which we impose to it, so that what we call organism remains a stillborn entity at best. The second challenge is creating a formal language suited to represent the organism while taking into account all its quantitative and qualitative characteristics.

Consequently, to progress in the understanding of the organism, it is first essential to integrate two data. The first one being that both the questions “what is the living?” and “how does the living arise?” are connected. In other words, before being able to apprehend correctly the emergence of life, it would be necessary to know how to model it, almost through a theoretical biology approach. The second datum is related to finding an appropriate language which is capable of describing the organism in all its dimensions.

In this present work, we want to find answers to the first list of Bedau's questions through a more integrative definition of the living which enables us to think of its mode of emergence from the nonliving in a coextensive way. For this, we propose a categorical model of the organism. This seems to be the most suitable language at the current stage of knowledge in describing such a phenomenon.

To formalise our proposal, we use a branch of mathematics called category theory. A category is a structure that appears like a directed graph, which consists of objects and arrows between them. However, in a category, two paths from A to B may be declared equivalent in a commutative diagram. Beside, a functor is a mapping from one category to another that preserves the structures.

As far as our main purpose is to unit entities in a special bigger one, this requires encoding interfaces, functional relationships, and transfer of data, extensive and intensive properties. In short, to convert an organism appearance into the ontology of category theory, we need concepts that allow us to group and lay out things. These concepts are best

captured by pushout and its dual pullback expressed in terms of diagrams of arrows, which are special types of more general constructs known as colimit and limit respectively.

In a category  $\mathcal{C}$ , the pushout (figure 1) for two morphisms  $f: A \rightarrow B$  and  $g: A \rightarrow C$  is an object  $D$ , and two morphisms  $j: B \rightarrow D$  and  $k: C \rightarrow D$ , such that the square commutes ( $f \circ g = j \circ k$ ); and for any objet  $D'$  and pair of morphisms  $j': B \rightarrow D'$  and  $k': C \rightarrow D'$  satisfying  $j' \circ f = k' \circ g$ , there is a unique morphism  $h: D \rightarrow D'$  such that diagram commutes. A dual is obtained by reversing the arrows. A complete presentation of category theory can be found in Lawvere and Schanuel (1997), and Ehresmann and Vanbremeresch (2007).

Figure 1

Pushout diagram

Three intuitions guide our approach of the living. First: a living organism transcends its material template. Second: it is a hierarchical multi-scale system within an environment (Cottam et al. 2004). Third is the idea of closure or autonomy, which was extensively analysed *inter alia* by Robert Rosen (1991). We argue that these different intuitions and characteristics of an organism are best described through the importance of colimits, functors or identity arrows. From a single cell to a complex multicellular organism such as a plant, a repetitive multi-scale hierarchical concept is found embedded, the one in the other, giving the hierarchical system a self-similarity dimension.

An organism appears with the advent of the closure of the system. From the categorical viewpoint, it happens with the instantiation of a functor called the “quale identity”. The quale can be illustrated by a diagram using the categorical idea of identity arrow. Although there are other arrows with the same object for domain and co-domain, the identity arrow defines a unique relationship of the object with itself.

The dual of the quale identity is represented by the hierarchical multi-scale system. While the colimit, which is a bottom-up process, constructs the system, the quale identity is a top-down process which consolidates it. At first, the final system appears as a resulting entity of a pullback and a pushout fitting. The difference between these two characteristics is that the hierarchical system has a quantitative nature, whereas the quale identity is a qualitative function. To summarise, let  $(a)$  be a hierarchical system in its environment  $(A)$ , and its identity quale  $(I_{qa})$ , an organism can be formalised as  $I_{qa}(a, A)$ .

The hierarchical system and the quale identity work as two semi-categories. If we reduce the hierarchical system to a collective link  $(L)$ , as the quale identity is a reduction of the top-down process, both morphisms become endofunctors. Their correlation depends on natural transformations, which are morphisms between functors. From these data, a model of the organism can be represented by the figure 2.

Figure 2

Formal categorial representation of an organism where  $(K)$  is the colimit of the multi-scale hierarchical system  $(a)$ .  $(P)$  is the pattern of subsystems of  $(a)$ .  $(I_{qa})$  is the identity quale of  $(a)$ , and  $(L)$  is a set of links from  $(P)$  to  $(K)$ . The dualistic aspect of the entity is overcome by a set of natural transformations  $(F, G)$  which interplay between  $(I_{qa})$  and  $(L)$  and by which the organism becomes an evolutionary unit (according to Cazalis, 2013).

With this model of the organism, we can better comprehend its mode of emergence from the nonliving. We propose that in a given environment, there are arguably two essential events in the advent of organisms. One is the formation of the multi-scale hierarchical system having the characteristics  $(C_T)$ , and the instantiation of the quale identity within it. The second event constitutes a real heart of the system, giving it autonomy and its robustness, which are the first characteristics of the individual. It is not necessary that the hierarchical system be perfectly organised; it is actually preferable that it has certain plasticity. Indeed, the quale identity exercises a canopy function within the organism. The canopy function has two main aspects. First, it is a function

which comes from the very system itself and characterises the quale. Secondly, as a functional image of the hierarchical system, it has a compensating role especially when the system has not reached its fluctuating balance; that is its coherence. On the same note, we assume that the characteristics  $(C_T)$  do not mean a full coherent system because once the quale identity is instantiated; it sustains and perfects the integration.

The interaction between the endofunctors  $(L)$  and  $(I_{qa})$  allows the organism to be an evolutionary unit. Changes in  $(L)$  from modifications to the environment or by natural destruction of its elements entails to their replacement or substitution to preserve the feature memorized in the quale.

In the same way, the quale could be subject to positive or negative interferences with other organisms present in the environment. As long as the characteristics of the hierarchical system are protected, the maintenance of the initial quale is guaranteed.

The interactions operated by a set of natural transformations entail an internal temporality, which constitutes the second characteristic of the organism. Depending on the evolution of the organism the area of the natural transformations is subjected to a process of complexification.

Finally, how does life arise from the nonliving is suggested by the very nature of the organism according to our model. Subsequently, this work analyses the quantitative and qualitative aspects of the organism; and the notions of autonomy and internal temporality. It proposes a composition rule for the quale identity in collective organisms and discusses the problem of critical threshold  $(C_T)$  with respect to the bottom-up approach that aims to assemble artificial cells from scratch using nonliving materials.

## Abstract

An important goal in the field of evolutionary computation and robotics is the development of systems that show self-adaptation in dynamically changing environments. However, adaptation to a changing or fluctuating environment is challenging and usually requires a dynamic solution. Here, we present a bio-inspired, agent-based controller driven by an artificial gene regulatory network that enhances the adaptability of robots in dynamically changing environments.

## Artificial genome

The Genome consists of two kinds of genes. The 'regulatory' gene is in charge of the regulatory functions while the 'structural' gene determines the phenotype of the robot through its gene expression product. The interaction between genes and the environment is based on the transcription factor binding process.

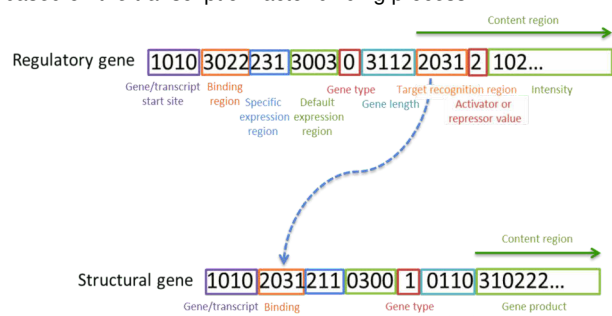

Figure 1. Artificial genome encoding the regulatory network. Any gene, irrespective of its type, consists of the following components: a transcription start site, a gene identifier (type), a gene length region, a binding site region, an expression level region (default and gene-specific expression region), and a content region which is different for structural, regulatory and signaling genes.

## Results & Conclusion

To demonstrate the advantages of our bio-inspired controller, we also developed an artificial life simulation platform that can provide a dynamically changing environment. Simulation results show that the bio-inspired GRN based controller has a better average adaptability than an evolutionary artificial neural network (ANN) based controller and a signal-based controller when placed in the same dynamically changing environments. Based on the experimental results, we believe the dynamics and the feedback loops of the GRN have great potential to enhance the adaptability of individual organisms in a changing environment.

## Agent based GRN

The dynamics of the GRN, encoded by the artificial genome, and its interaction with the environment, are modeled by an agent-based system.

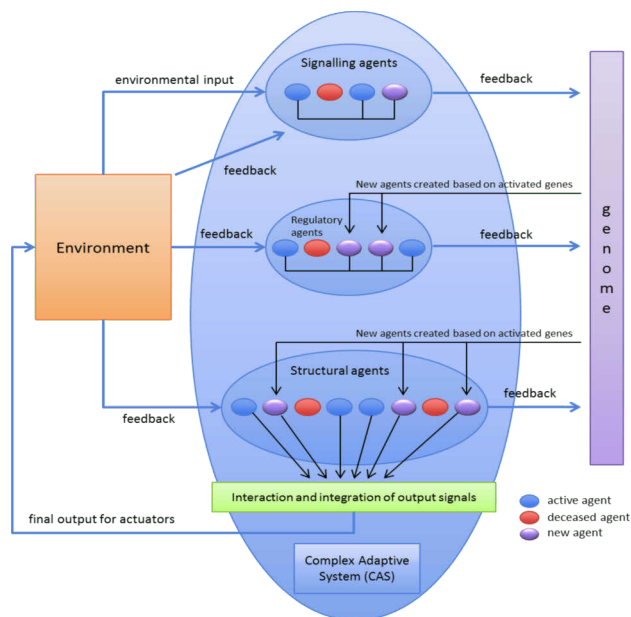

Figure 2. Agent based system modeling the condition dependent instantiation of the GRN encoded by the artificial genome. Three different kinds of agents are distinguished, namely signalling agents modeling the interaction between the environment and the artificial genome, regulatory agents that constitute the active part of the GRN encoded by the artificial genome, and structural agents that translate the encoded information of a structural gene to an output signal, which drives the actuators (e.g. wheel) of the robot. The agents based level is also essential in establishing the feedback from the environment to the system through the agents adaptability values which affect both the agents lifetime, genomic encoding, and mutation rate.

Figure 3. Average energy levels for the three different controllers during runtime. The Y-axis represents the average energy level of the robots while the X-axis represent running time measured in time steps. The red line shows the result for a single simulation experiment based on the GRN controller; the blue curve shows the result for the experiment based on the ANN controller, and the purple curve shows the result for the experiment based on the simple non-evolvable signal-based controller.

# CARDINAL-E: AIS Extensions to CARDINAL for Decentralised Self-Organisation for Network Security

## Extended Abstract

This paper extends the CARDINAL architecture by Kim et al. (2005) to CARDINAL-E. CARDINAL-E keeps the innate immune system behaviour at every computer on the network and relocates the adaptive immune system behaviour to higher performance computers. Two paradigmatic shifts are achieved by this modification. First is the shift from standalone to supportive, otherwise considered as architecturally static to dynamic. This leads to an additional layer of homeostasis at a network-wide level. The intended effect is to leverage unused capacity on networks of heterogeneous machines. Secondly, the change represents a subtle granular shift from “each computer has identical immune system components” to “the network (as a whole) carries all the immune system components”. This is a synthetic network-wide “body” where organs (CARDINAL’s Periphery and Lymph Node components) are finite and proportionate in quantity, and evolve their behaviour over time.

Figure 1: A simplified illustrative example of the CARDINAL-E architecture in a small network. Inputs are received at each host. Unknown inputs with danger signals are transferred to lymph nodes for further analysis. In larger networks  $l < n \wedge l > 1$  is true, where  $l$  is the set of hosts with lymph nodes and  $n$  is the quantity of hosts. Host 2 illustrates a single CARDINAL host as proposed by Kim et al. (2005).

## Problem

A problem for moderately sized real-time distributed applications is maintaining enough computational capacity for decision analysis. We are addressing the performance requirement for real-time security applications in industrial control system (ICS) network and supervisory control and

data acquisition (SCADA) network scenarios. These networks commonly have combinations of legacy and new systems that need real-time protection. SCADA networks, by definition are remotely and sparsely located. Balancing computational effort is often a solution to the computation capacity problem. These same applications and networked computer systems are also targeted by hackers and malware. In this case the load balancing solution needs to be robust (no single point of failure) and adaptive to a number of compromised systems or disconnected network segments. Therefore, we need an architecture (like CARDINAL-E) that would support these application scenarios whilst requiring minimal computational resources.

## Approach

To achieve these aims we worked toward a decentralised and fault tolerant framework and selected an immune system inspired approach. The CARDINAL framework against malicious worms by Kim et al. (2005) provided an artificial immune system (AIS) base for this self-organisation and the malware self-healing functionality. CARDINAL offered malleability to network-based decentralised decision making applications and embodied immunological danger theory, see Matzinger (1994). Our work employed the conceptual AIS framework in Stepney et al. (2005) to aid the complex (distributed) systems framework development. This led us to consider the decentralised self-management and self-organisation mappings to immune system flow and signalling regulatory mechanisms and other biological processes including cell potency and conscious awareness. We also considered these mappings to the engineered robustness of recent peer-to-peer botnet architectures particularly for their approaches to minimising their impact on network traffic, see Wang et al. (2010).

## Method

In the proposed method, the key modifications to Kim et al.’s framework are the conditional removal of lymph node behaviour from *some* computers and periodic reorganisation of the behavioural roles. Figure 1 simplifies the proposed architecture. An engineered implementation of CARDINAL-

E will only accept the networked application with multiple Lymph Node components.

The reorganisation process proposed enables the reactive lightweight CARDINAL component (input sensor, signatures, etc.) to execute on all CARDINAL-E hosts and the heavier-weight analysis (diagnosis, etc.) to execute on fewer selected hosts. A reorganisation procedure of distributed system roles requires routines for initialisation, transfer of roles, periodic data analysis, historical data analysis, decentralised decision making, secure data transfer, etc. We expect suitable metrics for the role transfer decision to be CPU, memory, disk space and network load parameters recorded and averaged over given time periods. Further careful consideration of these routines will potentially lead to the occurrence of adaptive homeostasis and the emergence of regulatory network activity cycles for a given network.

### Future Application

A future application of CARDINAL-E is to self-healing network security on industrial network types. This requires definition of the CARDINAL application. Kim et al.'s CARDINAL framework uses a population based model of dendritic cell and T-cell interactions to decide when to respond. The definitions of danger theory damage proposed by Kim et al. define bad or unwanted behaviour. The degree (severity and certainty) to which that unwanted behaviour has been experienced will determine the response category. CARDINAL leaves the definition of *strong* and *weak* responses, and response types open to the application designer. To close some of CARDINAL's open representations, Fu et al. (2007) introduced the MAAIS architecture as a derivative of CARDINAL. We intend to reuse Fu et al.'s following additions "length of attack time" to CARDINAL's damage certainty and severity factors; a two-tier damage threshold to decide whether attack analysis requests are handled locally (client) or remotely (server); a weighted equation to determine a damage value; and use of the ASK and TELL protocol for agent communications.

Furthermore, we describe the key representations of detection (antigen input vector), diagnosis (innate system damage decision vector) and experimental response. We represent antigen input as a statistically dimensionally reduced set of eight attributes from the KDD Cup '99<sup>1</sup> dataset. These attributes are {*protocol\_type*, *service* (*port number*), *flags*, *src\_bytes* (*received*), *dst\_bytes* (*sent*), *count*, *diff\_srv\_rate*, *dst\_host\_same\_src\_port\_rate*} which are collected over two second intervals. Appropriate attributes are summed over the interval using a connection identifier defined as  $\langle src\_ip+port+dst\_ip+port \rangle$ . We represent Kim et al.'s damage (necrosis) signal as network packet latency (to

local area and Internet hosts) and individual process loads (CPU and memory loads) where their values breach given thresholds. At this experimental stage, we use Kim et al.'s three effector T-cells to label responses. These are strong response (CD8<sup>+</sup> or cytotoxic T-cells), weak response (helper 2 T-cells) and assist a strong response (helper 1 T-cells), Kim et al. (2005).

### Conclusion

This work leads toward a self-healing system against novel attacks and malware on ICS and SCADA network scenarios, such as dynamic military and defence computer networks and manufacturing industrial networks of various scales. Further work is required to define the CARDINAL-E reorganisation routines and the immune system inspired decentralised decision making, and the CARDINAL diagnosis and response mechanism for novel attacks must be explicitly addressed.
